ABSTRACT

A 25-d trial was performed to assess the effects of machine and hand milking on behavior, and milk yield and composition of mares; the trial involved 8 Murgesse mares. Milk yield was higher (7.69 vs. 4.91 kg) and milking time was shorter (1.80 vs. 5.40 min) in machine-milked than in hand-milked mares. Machine milking of mares also resulted in a greater fat content of milk (1.63%) than did hand milking (1.06%). Milking system did not affect casein content, nitrogen fractions, or somatic cell counts. No differences in behavioral activities and in response to humans emerged. Results indicate that machine milking of mares could improve the yield and gross composition of horse milk, without adverse consequences on mare behavior and response to humans.

Key words: Murgesse mare, milk yield and composition, milking system, behavior

INTRODUCTION

Mare's milk was traditionally used by nomadic people from the former Union of Soviet Socialist Republics, Mongolia, and Eastern Europe for human nutrition and then for therapeutic purposes in the countries where it was produced (Doreau and Martin-Rosset, 2002). Mare's milk, because of its nutritional characteristics, is a product of great interest not only for human consumption (children, adults, or convalescent consumers), but also as a therapeutic agent and for cosmetic purposes. Recently, there has been increasing interest in mare's milk for human nutrition. In particular, the use of mare's milk has been proposed as a substitute for cow's milk in allergic children, as a substitute for mother's milk for premature newborns, and for other therapeutic purposes (Curadi et al., 2001; Doreau and Martin-Rosset, 2002). In Western Europe, the Haflinger is

considered the main dairy breed (Doreau and Martin-Rosset, 2002), but the increase in the utilization of mare's milk as a formula for children with allergies could allow the exploitation of a local horse breed such as the Murgesse. The Murgesse is a light draft and riding horse reared in the area of Murge (Apulia, southern Italy). Murgesse horses are usually black, and sometimes gray, and they originated from Oriental-type studs crossed with local mares (Mason, 1996). Murgesse horses are a genetic population selected for saddle (Pieragostini et al., 2005) and Murgesse mares are not accustomed to a milking routine. Mechanization of many agricultural practices has led to a gradual decline of this breed, which is threatened with extinction at the present time. In the last few years attempts have been made to characterize the milk composition of Murgesse mares to promote this local breed (Pinto et al., 2001).

The cisternal compartment of the mare has a very low capacity compared with other dairy animals. Therefore, the use of mares for milk production requires frequent milking, at 2 to 3 h intervals, and the foals are allowed to suckle the mares for the rest of the day (Doreau and Martin-Rosset, 2002). Previous studies noted that machine milking is more efficient than hand milking of mares, even if the mares are difficult to adapt to the machine-milking procedures after foaling (Le Du, 1986). In mares the milking ejection reflex is related to the expression of maternal behavior. The transition from suckling to milking can be improved by milking the mare with the foal in front of her, or milking one teat while the foal is suckling the other, or offering oats during machine milking (Le Du, 1986). In contrast, alveolar milk ejection in cows is induced by the oxytocin that is released in response to tactile teat stimulation by the calf, hand, or milking machine (Bruckmaier, 2005).

Success of milking procedures depends on the manageability of mares, which reflects the stockman's ability to impose routine handling of mares and the affinity of the mares to humans (Lansade et al., 2004). Humans can induce fear in animals because of their size and quick movements; improper handling can lead the horse to express dominance behaviors over humans or

to consider humans as other horses (Jezierski et al., 1999; Rushen et al., 1999).

The aim of the present experiment was to evaluate the effects of machine and hand milking of Murgese mares on milk yield and composition, and on mares' behavior and responses to humans.

MATERIALS AND METHODS

Animals and Experimental Treatments

The trial lasted 25 d and involved 8 Murgese mares (55 ± 8 DIM), randomly selected from an extensively managed herd in southern Italy (Gioia del Colle, Bari, Italy; $40^{\circ}48'0''$ N and $16^{\circ}56'0''$ E). The mares involved in the experiment were in parity 4 to 6 and had a live weight of ~ 550 kg. The animals were divided into 2 groups of 4, balanced in terms of parity and stage of lactation, and subjected to hand or machine milking. Mares were maintained on a natural pasture during the day together with their foals, and kept in individual straw-bedded boxes of $3 \text{ m} \times 3 \text{ m}$ at night. Water was available from troughs at all times. The mares had not previously been subjected to any milking procedures. Both hand- and machine-milking procedures were carried out by milking the udder after manual stimulation to activate the milk ejection reflex, and in the presence of the foal that had been previously prevented from suckling for 3 h by a muzzle. During each hand- and machine-milking session, mares were given small quantities of concentrate (~ 300 g per milking). A milking machine for sheep adapted to a mare's udder was used, with a mean vacuum level of 45 kPa, a pulsation rate of 120 cycles/min, and a pulsation ratio of 1:1. Milk yield and time taken for udder emptying (i.e., milking time) were individually recorded daily for both hand- and machine-milked mares. Milk yield was recorded by means of graduated measuring cylinders. Individual milk samples from both hand- and machine-milked mares were collected on d 1, 5, 10, 15, 20, and 25 of the trial, twice a day at 1000 h and then at 1300 h. Milk samples, consisting of proportional volumes of the 2 milkings, were individually collected from bucket milk in 200-mL sterile plastic containers after cleaning and disinfecting the teats (70% ethyl alcohol) and discharging the first streams of foremilk. Both hand and machine milking of the mares were performed in turn by 2 stockmen.

Analysis of Milk

A total of 96 milk samples were sent to our laboratory by means of transport tankers at 4°C and analyzed for their chemical composition. The following measurements were carried out on milk: pH, fat and lactose

content using an infrared spectrophotometer (MilkoScan 133B; Foss Electric, Hillerød, Denmark) according to the IDF (1990) standard, and SCC using a Foss Electric Fossomatic 90 cell counter according to the IDF standard (1995). Total N, noncasein nitrogen (NCN), and NPN were determined by standard procedures using the Kjeldahl method (IDF, 1993). Total protein was calculated as total N $\times 6.38$, CN nitrogen was calculated as the difference between total N and NCN (multiplied by a conversion factor of 6.38), and whey protein as the difference between NCN and NPN (multiplied by a conversion factor of 6.38).

Behavior of the Mares

At d 5, 15, and 25 the behavioral activities of mares were monitored using a scan sampling procedure, to assess the effect of hand and machine milking on behavioral patterns of the animals. During the pretrial phase, the behavior of each individual mare was monitored daily to test the presence or confirm the absence of behavioral abnormalities. On each observation day, the observer walked slowly in front of each box from a distance of 4 m and recorded the general behavioral activities of the mares, while trying to be not perceived by the mares. The behavior of each individual mare was video-recorded for 4 h (from 1100 to 1500 h) by a trained person and scan samples were taken every 10 min. At each observation period, the time the mares spent in standing, feeding, and stereotyped pacing was recorded. Neighing, defecating and urinating, litter eating, crib eating, wind sucking, weaving, and kicking are events of short duration; therefore, their frequency of presentation was measured by continuous recording for the whole 4-h period and expressed as the number of events recorded in each activity.

On d 10 and 20, mares were tested for their responses to 5-min open field tests in the presence of a human, who was 1 of the 2 stockmen involved in milking the animals. During the tests, the time spent in proximity to the person (within 2 m of the human stimulus) and the time spent away from the person (more than 5 m from the human stimulus) were recorded, and the number of flight attempts was noted.

All procedures were conducted according to the guidelines for the ethical use of animals in applied animal behavior research on the protection of animals used for experimental and other scientific purposes (Sherwin et al., 2003).

Statistical Analysis

All the variables were tested for normal distribution. Somatic cell count and scan-sampled behavioral data

were evaluated on log₁₀ transformed data to homogenize variance. Milk and behavioral variables were then processed using the GLM procedure of SAS (SAS Institute, 1999), with milking system, time of sampling, and their interaction as sources of variation. Individual animal was nested within each treatment. When significant effects were found ($P < 0.05$), Student's *t*-test was used to locate significant differences between means.

RESULTS AND DISCUSSION

Milk Yield and Composition

Results from the present trial showed that the milking system had an effect on the yield and gross composition of mare milk without interfering with the human-mare relationship and mare behavior. Milk yield and composition, and milking times recorded during the 2 daily milk samplings are reported in Table 1. The machine-milked mares gave higher volumes of milk ($P < 0.05$) and took less time ($P < 0.01$) for udder emptying than the hand-milked mares. Milk yield decreased starting from d 5 of the trial until the end of the experiment ($P < 0.001$), as an effect of the advancement of lactation. In addition, machine milking of mares resulted in a greater fat content of milk ($P < 0.01$). The milking system did not affect lactose, total protein, and CN contents, nitrogen fractions, or SCC. An effect of time of sampling was found for pH, CN content, and SCC ($P < 0.001$) that decreased with the advancement of the study period in both groups, and for whey protein and NCN contents ($P < 0.001$) that increased as the experiment progressed. Time of sampling and the interaction of time of sampling by milking system affected the lactose and protein contents and the NPN fraction, which underwent marked changes through the study

period according to different trends in hand- and machine-milked mares. In particular, lactose content increased with the advancement of lactation, being greater in hand-milked than in machine-milked mares, whereas an opposite trend was observed for protein content. The NPN fraction tended to decrease with the progress of lactation. Previous results agree with the observations of Martuzzi et al. (2004) when comparing early lactation with late lactation milk in nursing mares.

Results indicate that there was better milk removal from the udder in the machine-milked mares. In fact, the fat content in the milk from hand-milked mares in the present trial was comparable to that recorded by Pinto et al. (2001) in hand-milked Murghese mares. This indicates that hand milking of mares may result in incomplete emptying of milk from alveoli and galactophorus ducts. It is well known that the cisternal component of the mare's udder has a very low capacity and the main part of milk is alveolar milk. The maximal recovery of milk is obtained by good conditioning of mares to milking routines (Doreau and Martin-Rosset, 2002). Complete milking of the mare's udder requires a good concentration of oxytocin release that can be obtained by the presence of the foal during the milking procedure and the choice of proper working parameters of the machine. Our trial demonstrates that the machine milking of mares may be more efficient than hand milking. The better performance of machine-milked mares could be attributed to the proper choice of the technical parameters of the mechanical milking and to the reduced technical competence of stockmen to hand milking of mares. Indeed, the stockmen performing hand milking were not accustomed to dairy practices, and may have induced disturbances in the mares. Milk ejection can be disturbed by inhibition of oxytocin re-

Table 2. Least squares means ($\pm$ SEM) of mares' responses to humans during the open field tests at d 10 and 20 in mares subjected to hand or machine milking

Behavior	Hand milking	Machine milking	SEM	Effect

Time spent ≤ 2 m away from human, %	21.7	22.8	8.0	NS	NS	NS
Time spent > 5 m away from human, %	74.5	68.3	8.3	NS	NS	NS
Flight attempts, n/5 min	4.9	4.1	1.9	NS	NS	NS

lease because of emotional stress (Bruckmaier, 2005). In cows, the fear of humans has been shown to reduce milk yield (Rushen et al., 1999). In addition, evidence exists that animals handled by stockmen in an aggressive manner develop a learned nervousness toward humans (Hemsworth et al., 1994, 1995). From this point of view, stockpersons untrained in the hand-milking procedure could have detrimental effects on milk ejection in Murghese mares that are unaccustomed to milking routines.

Behavior of the Mares

Differences did not emerge in mare responses to human stimulus (Table 2) with respect to milking system. Mares spent more time (3-fold longer) far away from than in proximity to stockpersons (71 vs. 22%) and tried to escape from humans with a high frequency (4.5 times, on average, over the 5-min duration of open field tests). Thus, the mares' responses to humans indicate the absence of a good relationship between the animals and stockmen, irrespective of the milking system. Previous observations highlighted the limited confidence of mares toward humans. A number of studies have dealt with the effects of aversive or positive handling on animals' welfare and productivity: some authors found that

animals subjected to extra handling develop a positive reaction toward the stockmen with beneficial effects on their production compared with animals only subjected to routine handlings (Rushen et al., 1999; Simpson, 2002; Lansade et al., 2004). In lambs, when assessing the effect of gentle handling on the development of the human-animal affinity, no signs of closer familiarity for persons emerged (Caroprese et al., 2006). Accordingly, Mal et al. (1994) found that increased preweaning handling of foals had no effect on their learning ability and manageability.

The observation of mare behavior in boxes (Table 3) did not show differences between groups that could be directly ascribed to the milking treatment: hand-milked mares appeared to be more vigilant as indicated by longer time spent standing alert ($P < 0.01$) and shorter time spent eating ($P < 0.05$) than the machine-milked mares. In fact, as vigilance declines, animals have time available for other activities: many trials found an increase in feeding time as vigilance declined (Treves, 2000). On the other hand, the greater number of neighs registered in the machine-milked ($P < 0.05$) compared with the hand-milked mares could be interpreted as a sign of reactivity—a way to attract attention and to relay information about the state of the surrounding environment (Waran, 2001). A previous study cited by

Wolff et al. (1997) reported the whinny as a social search and contact call of horses occurring when social partners are separated. No differences emerged between machine-milked and hand-milked mares for anomalous behaviors.

CONCLUSIONS

Growing interest in mare's milk for human nutrition could be an important tool for recovery of the Murgesse horse breed. Results from the present experiment demonstrated that machine milking of mares was more efficient than hand milking, resulting in a higher yield of fatter milk and in a more rapid udder emptying. The higher production efficiency displayed in machine-milked mares could be because of the proper choice of technical parameters of the mechanical milking and the reduced technical competence of stockmen to hand milking of mares. The open field tests highlighted a poor relationship between mares and stockmen, but the milking system did not influence the behavioral patterns and responses of animals to humans.
