ABSTRACT

Nine organic acids (formic, pyruvic, lactic, acetic, orotic, citric, uric, propionic, and butyric) were analyzed during ripening of pickled White cheese for 12 mo by high-performance liquid chromatography with a reverse phase C18 (120×5-mm) column and UV detector. The level of total organic acids showed an increase along the ripening period, but its composition varied during the process. Initially, lactic acid accounted for 95% of the total, after 9 and 12 mo of ripening, butyric acid constituted 20 and 27% of the total, respectively. Each organic acid presented a characteristic pattern of change during ripening. Discriminant analysis classified cheeses according to their age. Stepwise regression analysis allowed estimation of the ripening time of samples according to their organic acid levels. (Key words: organic acid, pickled White cheese)

INTRODUCTION

Cheese ripening is characterized by a series of complex physical, chemical, and microbiological changes affecting the principal components of the cheese. Extensive research has been directed at finding and evaluating microbiological and biochemical parameters by which cheese could be classified and whereby uniform cheese quality could be established (Adda et al., 1982; Farkye and Fox, 1990; Seitz, 1990). Attention has been given to the mechanisms by which cheese curds become distinctively flavored cheeses, but maturation processes are not well understood for most cheeses due to the heterogeneous nature of the product. Numerous active microbial enzymes are present together with the metabolites; the changes in ripening depend on the biochemical conditions of curd, i.e., water activity, pH, oxidation-reduction potential, mineral contents, and several other factors including ripening temperature, level and method of salt addition, and the nature of secondary microflora (Law, 1984).

The acceptability of cheese depends largely on the flavor formed during ripening. The flavor profiles of cheeses are complex and are variety- or type-specific. These profiles are influenced by many substances, e.g., organic acids, sulphur compounds, lactones, methyl ketones and alcohols, and phenolic substances (Seitz, 1990; Urbach, 1993). The organic acids, important flavor substances of most aged cheeses, form as a result of the hydrolysis of fatty acids, normal bovine metabolic processes, and bacterial growth, or appear by addition of acidulants during cheesemaking (Adda et al., 1982). Quantitative determination of organic acids is important to flavor studies for nutritional reasons and as an indicator of bacterial activity. Hough et al. (1996), working on Reggianito grating cheese showed that total aroma intensity was correlated with organic acid concentrations.

Attempts to use HPLC profiles as the classification parameter of maturity in cheese varieties have been reported by Pham and Nakai (1983) and Mohler Smith and Nakai (1990). With the use of HPLC, a number of authors have attempted to use organic acid content as an indicator of microbial metabolism and classification parameter of various cheese types for their age (Marsili, 1985; Panari, 1986; Bevilacqua and Califano, 1989; Lombardi et al., 1994; Lues and Botha, 1998; Califano and Bevilacqua, 1999).

Pickled White cheese is the most important cheese variety manufactured in Turkey. Due to economic and consumer preference reasons, this cheese and its manufacture have evolved somewhat differently among producers in Turkey. Major research and process improvement efforts have been carried out to ensure standard quality. Generally, the cheese is stored at 4 to 5°C for 3 mo. The aging period can be extended to 12 mo depending on the raw milk quality, processing methods of cheesemaking, ripening temperature, etc., in order to form excellent flavor in cheese. The sensory properties of pickled White cheese vary widely. In particular, organic acids contribute to the flavor of most aged cheeses, including pickled White cheese.

The aims of this study were 1) to investigate the changes in organic acids content (formic, pyruvic, orotic, uric, lactic, acetic, citric, propionic, and butyric) by reverse-phase, HPLC during pickled White cheese aging; and 2) to evaluate the contribution of organic acids to maturity of the pickled White cheese. For this purpose, discriminant analysis was applied to our HPLC data to investigate whether classification of pickled White cheeses according to their ripening time could be done solely on the organic acids. Several authors have used the discriminant analysis successfully for classification of maturity of Cheddar (Pham and Nakai, 1983), frozen Cabrales (Alonso et al., 1987), Port Salut Argentino (Bevilacqua and Califano, 1992), Reggianito (Lombardi et al., 1994), and low-moisture Mozzarella (Califano and Bevilacqua, 1999) cheeses.

MATERIALS AND METHODS

Cheese Making

Twenty-one cheeses were produced at a local dairy plant (Can Dairy Products Plant, Torbali, Izmir, Turkey) according to the following procedure: Pasteurized milk (2.6% milk fat) was cooled to 38°C and pumped into a cheese vat. Cheese starter DVS R-703 (Chr. Hansen Laboratorium, Denmark) was added at the rate of 0.002% along with 0.2% CaCl₂ and 0.015% calf rennet CLB 1000K016 (DSM, Delft, Netherlands). Cheeses were produced in one batch to minimize variability between cheese samples.

The starter consisted of Lactococcus lactis ssp. cremoris and Lactococcus lactis ssp. lactis in equal rates. Also, 0.01% liquid yogurt starter culture was added (Aegean Univ., Faculty of Agric., Dept. of Dairy Technol., Izmir, Turkey), containing Streptococcus salivarius ssp. thermophilus and Lactobacillus delbrueckii ssp. bulgaricus in equal rates.

When the curd was sufficiently firm (~45 min), it was cut. Afterwards, the curd was molded, and the whey was drained by pressing. The drained cheeses were immersed in brine containing 15% salt for 4 h and placed in PVC boxes for 2 d at 15 to 17°C for preaging. The cheeses were then packed in 1-kg cans, filled with brine (12% salt), and stored at 4 to 5°C for 12 mo. The water content of cheese samples was maintained at 57 to 59% throughout the 12 mo of the experiment. Initially, the mean pH value of cheese loaves was 5, and decreased to 4.5 at the end of 12 mo of storage.

Sample Preparation

At a preestablished time, three cheese cans were opened, and about 100 g of a representative sample was grated. A 7-g grated sample was added to 40 ml of buffer-acetonitrile mobile phase (0.5% (wt/vol) (NH₄)₂HPO₄ (0.038 M) − 0.4% (vol/vol) acetonitrile (0.049 M), at pH 2.24 with H₃PO₄), extracted for 1 h, agitated on a shaker (model 75, Burrell Scientific, Pittsburgh, PA), and centrifuged at 6000 × g for 5 min according to a modification of the method of Bevilacqua and Califano (1989). The supernatant was filtered once through Whatman #1 filter paper and twice through a 0.45-μm membrane filter (Sartorius SM 11606, Göttingen, Germany), and then used directly for HPLC analysis. Triplicate analyses were performed on all samples.

HPLC Analysis

A Jasco liquid chromatograph (LC-900 Series, Jasco International Co., Hachioji, Tokyo, Japan) was equipped with a model H-980-01 holder that accepts Rheodyne valves, 7124 injector-fitted with a 20-μl sample loop, a Jasco PU-980 solvent delivery system, and a Jasco UV-980 detector. The detector was set at 214 nm.

According to akalin et al. (1997), operating conditions were: mobile phase, aqueous 0.5% (wt/vol) (NH₄)₂HPO₄ (0.038 M) − 0.2% (vol/vol) acetonitrile (0.049 M) adjusted to pH 2.24 with H₃PO₄; flow rate 0.3 ml/min; ambient column temperature; and chart speed, 0.8 cm/min. A reverse-phase Machery Nagel C18 (120 × 5 mm)
A typical high-performance liquid chromatogram of organic acids for pickled White cheese is shown in Figure 1.

Statistical Analysis

Nine organic acids and their age scores at seven age-points with three replicates (9 × 7 × 3 = 189 observations) were considered during statistical analysis.

First, discriminant analysis was applied to the data, which consisted of changes in organic acids during ripening of pickled White cheese. Our aim was to determine whether the classification of the cheese according to ripening time could be solely due to organic acids. Stepwise discriminant analysis was preferred to obtain the list of potential discriminating organic acids to form the discriminant functions. During the stepwise procedure, Wilk’s Λ, which is a multivariate measure of group differences over several variables, was used as a selection criterion to determine the addition or removal of variables in the discriminant function. At each step, an organic acid was either added or deleted from the discriminant function according to the value of Wilk’s Λ. For better visualization, the canonical scores were plotted in discriminant space. Fisher discriminant functions comprising classification coefficients and constants were given for each ripening time to classify the raw data in terms of maturity of the cheese. Canonical discriminant functions, standardized as mean score of zero and within group variance of unit, were also calculated for assessing the relative importance of discriminator variables forming the discriminant function.

Second, stepwise regression analysis was carried out using organic acid concentrations to determine which organic acids were significant predictors for the ripening time. Probabilities of F values to add and remove independent variables into the regression model were 0.05 and 0.10, respectively.

SPSS for Windows statistical software (SPSS, 1997) was used for all statistical analyses in this study.

RESULTS AND DISCUSSION

A typical high-performance liquid chromatogram of organic acids for pickled White cheese is shown in Figure 1.
Table 1 shows the retention time (Tr), coefficient of determination ($R^2$), and organic acid recovery (%) of the cheese samples. Excellent linear responses ($R^2 > 0.998$ changing from 0.9982 to 0.9999) were found over a wide range of concentrations for all organic acids. The concentration ranges of organic acid standards were 10 to 70 μg/ml for orotic and uric acids, 1000 to 5000 μg/ml for citric, 50 to 1000 μg/ml for formic and acetic, 10 to 200 μg/ml for pyruvic, 1000 to 20,000 μg/ml for lactic, 100 to 1500 μg/ml for propionic, and 100 to 10,000 μg/ml for butyric acid. Efficiency of the extraction procedure, measured by adding to a White cheese sample known amounts of standard solutions containing the acids, ranged from 86.3 to 98.7% (Table 1). High-recovery ratios were in agreement with other authors (Marsili, 1985; St-Gelais et al., 1991). Using the same extraction method, Lues et al. (1998) reported recovery rates ranging from 86.4 (butyric acid) to 94.3 (propionic acid) for the same nine organic acids in Cheddar cheese samples.

Average concentrations of total organic acids in cheese samples showed a marked increase between mo 1 and 9 of ripening (Figure 2).

Lactic acid concentration also presented a similar pattern of change, presenting a maximum plateau in the ninth month. Initially, it accounted for about 95% of the total organic acid content. The primary purpose of a dairy starter culture is to produce lactic acid from lactose at a high rate in the early stages, the lactic acid acting to inhibit contaminants (i.e., coliforms; Scott, 1986). Formation of lactic acid is essential for proper

Figure 3. Changes in (a) lactic and pyruvic acids (ppm); (b) propionic, citric, and butyric acid contents (ppm); (c) acetic and formic acid concentration (ppm); (d) orotic and uric acids (ppm) during ripening. SEM indicates standard error of the mean (A. S. Akalin, S. Gönç, Y. Akbaş).
manufacture, flavor development, normal ripening, and good keeping quality (Wong, 1974). After aging for 2 mo, lactic acid represented 76% of the total acids and 69% and 60% after ripening for 9 and 12 mo, respectively (Figure 3a).

Butyric and propionic acid concentrations increased as ripening progressed, although at different rates. A rapid increase specifically in butyric acid concentration was responsible for higher organic acid content especially for the last several months. While butyric acid represented 0% of the initial total organic acid concentration, it accounted for 18, 20, and 27% of the total organic acid content after ripening for 6, 9, and 12 mo, respectively (Figure 3b). Similar results were obtained for Cheddar, Swiss, Reggianito, and Port Salut Argen-
tino cheeses for lactic, propionic, and/or butyric acids (St-Gelais et al., 1991; Bevilacqua and Califano, 1992; Fedio et al., 1994; Lombardi et al., 1994).

The presence of free fatty acids of short-chain like acetic, propionic, and butyric acids is mainly related to the intensity of bacterial fermentation that took place during ripening. Butyric and propionic acid fermentations were the result of the lipolytic and especially proteolytic activity of starters and an abundant secondary microflora (Esponda et al., 1983). If the milk fat globule membrane was damaged during cheese making, lipolysis and release of fatty acids such as butyric acid would be facilitated (Caboni et al., 1990).

Formic acid was formed during the first month of ripening, then increased in the second month and remained fairly constant thereafter (Figure 3c). The initial increase in formic acid might be explained by the presence of Streptococcus salivarius sp. thermophilus, which produces formic acid from lactose (Thomas, 1985). Bevilacqua and Califano (1992), Lombardi et al. (1994), and Califano and Bevilacqua (1999) also observed a similar trend for formic acid in the beginning of ripening of Port Salut Argentino, Reggianito, and low-moisture Mozzarella cheese, respectively.

Acetic acid was produced in the second month and showed irregular changes thereafter, with a maximum content around 12 mo of aging and a minimum at 9 mo (Figure 3c).

Citric acid also showed irregular changes with a slight tendency to decrease during ripening (Figure 3b), similar to findings of Lombardi et al. (1994) for Reggianito cheese. This decrease might be explained by citrate metabolism. Citrate is involved in the Krebs or citric acid cycle, where it acts both as substrate and product. Citrate can be used as substrate by the starter to produce pyruvic and acetic acids (Adda et al., 1982). Lacto-
coccus lactis ssp. cremoris may utilize citrate.

Uric acid content remained fairly constant between the first and sixth months, rising sharply thereafter. Both uric and orotic acids concentrations were found to be highest at the end of ripening (Figure 3d).

Pyruvic acid content decreased during aging, except between the first and third months (Figure 3a). Py-

Table 2. Classification function coefficients (Fisher’s linear discriminant functions) for each ripening time.
ruvate is readily formed through the glycolytic pathway, but it also acts as substrate of several metabolic reactions such as the formation of formic acid, ethanol, and diacetyl, acetoin, and 2,3-butylene glycol (Marth, 1974).

By stepwise discriminant analysis, eight organic acids (formic, lactic, acetic, orotic, citric, uric, propionic, and butyric acids) were selected, but pyruvic was omitted by the program to be the most effective for discrimination of ripening time. Since six discriminant functions explained the total variances among discriminating variables, six canonical discriminant functions were used in the analysis; 100% of the variation among ripening time groups was accounted by these discriminating variables. Most of the variation is explained by the first three functions; 56% of the variance was explained by the first discriminant function, while second and third discriminant functions explained 29.9 and 9% of the variance, respectively.

All ripening time groups were discriminated separately by the program. There was no difference between the actual group of cheese and assigned group of cheese by discriminant analysis.

Classification functions were given for each ripening time in Table 2. Observations are assigned to the groups with the largest classification score. Discrimination score of any pickled White cheese sample in which ripening time and characteristics were unknown can be calculated by substituting acid contents, and that sample can be assigned to the ripening time group with the largest discriminant score.

Standardized canonical discriminant functions for assessing the relative importance of discriminator variables forming the discriminant function are given in Table 3. The greater the standardized coefficient, the greater the relative importance of variables. For example, the relative importance of orotic, uric, and butyric acids was greater than that of the other organic acids from function 1 in Table 3.

Although seven groups were discriminated by the program, Figure 4 shows that five subsets may be considered according to their acid contents: 1) young or fresh cheeses, between 0 and first month, characterized by a decrease in pyruvic, lactic, and citric acid contents and by an increase in propionic, butyric, and formic acid concentrations; 2) middle-aged cheeses, 2 to 3 mo, which correspond to a period in which pyruvic, lactic, citric, propionic, and butyric acid concentrations increased and acetic, formic, orotic, and uric acids decreased; 3) old cheeses (6 mo) characterized for a high lactic, propionic, butyric, formic, acetic, orotic, and extremely low citric acid contents; 4) and 5) long-ripened cheeses, 9 and 12 mo, respectively, samples of high total organic acid concentration, mainly because of the increase in first lactic, second butyric, and propionic acid contents for 9 mo, and further increase in butyric and propionic acids as well as relatively high concentration of lactic acid contents for 12 mo.

Butyric, propionic, orotic, and formic acid concentrations were found to be significant predictors of ripening time (T) by stepwise regression analysis. Estimated regression equation is:

\[
T = -0.475 + 6.472 \times 10^{-4} \text{butyric} + 1.368 \times 10^{-3} \text{propionic} + 1.520 \times 10^{-2} \text{orotic} + 3.807 \times 10^{-4} \text{formic}.
\]

The adjusted coefficient of determination and multiple correlation coefficient were 0.998 and 0.999, respectively.
