ABSTRACT

Blood vitamin A profiles, including concentrations of retinol and its active metabolite retinoic acid, were assessed during the peripartum period and during experimentally induced Escherichia coli mastitis in heifers. Serum retinol decreased in all animals in the immediate postpartum period and normalized within 1 wk after parturition. No significant changes were detectable in the concentrations of retinoic acid isomers during puerperium. Following intramammary E. coli infusion, all cows showed moderate symptoms of systemic disease besides the local signs of inflammation. The presence of a systemic acute-phase reaction was documented by fever, increase in serum amyloid A, and decrease in serum albumin. Retinol concentration in serum also decreased spectacularly during coliform mastitis, and the decline was clearly related to the timing of the acute-phase response. Moreover, a significant increase of all-trans retinoic acid, mirrored by a lowering of 13-cis retinoic acid, was detected during the same time period. The 9-cis isomer of retinoic acid was present in all samples, but it remained below the quantification limit.

Results confirmed the decrease in serum retinol during the peripartum period of dairy cows. Furthermore, the study established that profound changes in vitamin A metabolism occur during the acute-phase reaction of coliform mastitis in heifers. The bovine infection model reproduced the acute phase-related hyporetinemia, as previously observed in humans and rats. In addition, all-trans retinoic acid was found to be the most abundant circulating acid isomer during mastitis, providing an indication for a possible key role of all-trans retinoic acid in the modulation of the immune response.

(Key words: retinoic acid, peripartum period, Escherichia coli mastitis, acute-phase response)

INTRODUCTION

The importance of vitamin A in immune function and protection against infections is well established (Semba, 1998; Stephensen, 2001). Recent experiments using various animal models and cell lines suggest that retinoids modulate a variety of processes, including hematopoiesis, apoptosis, cytokine and immunoglobulin production, and leukocyte function (Semba, 1998). Retinol (ROH) represents the most abundant retinoid in blood, whereas retinyl esters (particularly palmitate) represent the most abundant storage form in the liver. The major established pathway of enzymatic retinoid activation involves hydrolysis of retinyl ester, reversible oxidation of the released ROH into retinal, and irreversible oxidation of retinal to retinoic acid (Blaner and Olson, 1994). The immunologic effects of vitamin A appear to be mediated primarily through its acid derivatives, which include all-trans retinoic acid and 9-cis retinoic acid (Petcovich et al., 1987).

Serum ROH levels are maintained within a fairly narrow range despite large fluctuations in dietary vitamin A intake and tissue stores. Only under extreme conditions, such as deficiency or intoxication, the homeostatically regulated ROH levels become affected. In humans, however, serum ROH concentrations were shown to decrease transiently during the acute-phase response to infection (Beisel, 1998; Mitra et al., 1998; Schweigert, 2001). This phenomenon can complicate the interpretation of serum ROH as an indicator of vitamin A status, and the concomitant assessment of acute-phase proteins seems therefore inevitable. Until now, little attention has been drawn towards the possible involvement of retinoic acid, the active metabolite of vitamin A, during infection and inflammation.

A variety of animal models, most of them involving rodents, have been used to study inflammatory diseases
and have been described in the literature. However, controlled infection and disease with living bacteria is rather difficult in these small animal species (Vandesuete-Van Messom et al., 1995). In recent years, cow models were developed to study the systemic inflammatory response induced by mammary tissue infection (Burvenich et al., 1988). The success of these models is widespread because of their reproducibility, high self-curing rate, and the facility to obtain samples allowing molecular, immunocytochemical, and pharmacological studies. Moreover, the severity of the systemic signs following IMI of cows with *Escherichia coli* can be standardized depending on the stage of lactation (Hirvonen et al., 1999) and parity (Mehrzad et al., 2002). A moderate level of systemic signs after intramammary *E. coli* infection can be obtained during midlactation, whereas a severe systemic response, sometimes leading to shock and death, is more prominent during early lactation. Older cows also show a large variation in severity during early lactation, whereas a moderate level of systemic signs is observed in heifers (Mehrzad et al., 2002). Severity classification can be obtained easily and accurately through measurement of the milk production in infected glands (Heyneman et al., 1990; Vandesuette-Van Messom et al., 1993) and is related to the increase in serum amyloid A (SAA; Hirvonen et al., 1999) and intensity of bacterial growth in the infected glands (Kremer et al., 1993).

This study was designed to define the blood vitamin A profile during the peripartum period and experimentally induced *E. coli* mastitis in heifers. Based on the hypothesis of a compensatory change in retinoid metabolism during inflammation, we especially focused on the retinoic acid isomers, the biologically active forms of vitamin A. For this purpose, a well-defined bovine IMI model with measurable but moderate level of systemic signs was used. Under these well-defined conditions, inference from the results is expected because the inflammatory response is a well-conserved process among vertebrates (Klasing et al., 1987).

**MATERIALS AND METHODS**

**Experimental Design**

*Animals and housing.* Eight clinically healthy Holstein-Friesian cows, each in her first pregnancy, were selected. All heifers were in their seventh month of pregnancy on arrival at the dairy farm. The heifers were on a system of zero grazing from arrival until the end of the experimental study. The course of calving was normal; no inflammatory processes were detected during puerperium. Animals were fed twice daily with a ration consisting of corn silage, apple pulp, hay, and water ad libitum. Concentrates (Sandilac; Dumoulin Voeders Sanders, Moorslede, Belgium) were distributed according to milk production. Machine milking was performed daily at 0800 and 1800 h, using a quarter milking device (Packo & Fullwood, Zedelgem, Belgium). The study was approved by the Ethical Committee of the Faculty of Veterinary Medicine (Merelbeke, Ghent University).

**Inoculation procedure.** Heifers were in their second to fourth week of lactation when challenge was performed. Before the intramammary *E. coli* challenge, animals were controlled to be free of major mastitis pathogens through 2 consecutive negative bacteriological examinations with a milk SCC below 200,000 cells/mL on quarter level. A stock of *Escherichia coli* strain P4:032 (Bramley, 1976) was maintained in lyophilization medium at −20°C. For experimental use, bacteria were sub cultured in brain-heart infusion broth (CM225; Oxoid, Nepean, ON, Canada) at 37°C during 3 consecutive days. The bacterial suspension was washed 3 times and finally resuspended in pyrogen-free PBS. On d 0, after morning milking, 6 cows were inoculated in the left front and rear quarters with a suspension containing 1.10⁶ cfu of *E. coli* P4:032 in a total volume of 10-mL pyrogen-free saline solution per quarter. Following disinfection of the teat ends with 70% ethanol containing 0.5% chlorhexidine, the bacterial suspension was inoculated into the teat cistern by means of a sterile teat cannula. After inoculation, the left quarters were massaged for 30 s to distribute the bacterial suspension in the mammary gland.

**Sampling Procedure**

Blood samples were drawn aseptically from the external jugular vein by venipuncture, either in evacuated tubes containing 143 IU of heparin or in plain tubes wrapped in foil (BD Vacutainer Systems, Plymouth, UK). Serum was obtained from clotted blood following incubation for 2 h at 37°C and subsequent centrifugation (1000 rpm, 30 min, 4°C). Serum samples were frozen at -20°C until analysis.

*Partus study.* Daily samples from each cow were collected for metabolic profile assay beginning 2 d before the expected calving date and continuing for 1 wk into lactation. Concentrations of retinoids, SAA and tumor necrosis factor α (TNF-α) were determined in serum.

*Mastitis study.* Blood and milk samples were collected once daily on d −7, −4, −1, 0, +1, +2, +3, +6, +9, and +13 relative to challenge. On the day of challenge (d 0), blood and milk samples were collected at 6, 12, and 18 h postinfusion (p.i.). Whole blood was used to determine the total blood leukocyte count. Retinoid, SAA, and albumin concentrations were quantified in...
Experimental Procedures

Serum retinoid concentrations. As a precaution to avoid photoisomerization, all sample manipulations were carried out in amberized tubes under dim yellow light. Retinoid analogues were analyzed simultaneously by high-pressure liquid chromatography-diode array detection, using the liquid-liquid extraction and mobile phase conditions as described by Van Merris et al. (2002). Briefly, following acidification of the serum, proteins were denatured with acetonitrile. ROH, all-trans (atRA), 9-cis and 13-cis retinoid acid (13cisRA) were extracted using a mixture of n-hexane and 2-propanol (6:5:1.5, vol/vol). The organic layer was evaporated, the residue dissolved, and retinoids were eluted on a Symmetry C18 column (Waters Corporation, Milford, MA). Serum retinoid concentrations were calculated from the chromatographic peak area ratios of each retinoid to the internal standard.

SAA and albumin. Serum amyloid A was determined by a commercial sandwich type ELISA kit (Phase SAA kit, Tridelta Development Ltd, Ireland) according to the manufacturer’s instructions. Serum albumin was quantified using radial immunodiffusion plates (Bethyl, Montgomery, TX), based on the Fahey and McKelvey (1965) technique. All samples were run in duplicate.

TNF-α. Concentrations of TNF-α in blood serum were measured by radioimmunoassay (Blum et al., 2000).

Total blood leukocyte count. The number of circulating leukocytes was counted in an electronic particle counter (Coulter Counter Z2; Coulter Electronics Ltd., Luton, England).

Quarter milk production. Daily quarter milk production, the yield of the evening and subsequent morning milking, was measured daily using a quarter milking device (Packo & Fullwood). The loss in milk production in the uninfected contralateral quarters on d 2 p.i. has been used as a criterion to classify cows as moderate or severe responders to experimental E. coli mastitis after parturition (Heyneman et al., 1990; Vandeputte-Van Messom et al., 1993).

Milk SCC. Milk SCC was determined using a fluoroperoelectronic method (Fossomatic 400 cell counter; Foss Electric, Hillerød, Denmark), which is based on the binding of ethidium bromide to DNA.

Colony-forming units in the inoculated quarters. The population level of E. coli in the infused quarters was determined by 10-fold dilutions of the milk sample in PBS. Ten microliters of the dilutions was plated out in duplicate on Columbia Sheep Blood agar (Biokar Diagnostics, Beauvois, France) and incubated at 37°C for 24 h. The obtained colony count was converted to colony-forming units per milliliter, based on the dilution factor.

Statistical Analysis

Partus study. A mixed model of SAS (version 8) was fitted to the retinoid, SAA, and TNF-α concentrations, respectively, with a day around parturition as the fixed categorical effect and cow as the random effect. The association between retinoid and SAA or TNF-α concentrations was investigated by a mixed model with SAA or TNF-α concentration as a continuous variable parameter and cow as a random effect. The association between retinoid and SAA or TNF-α concentration was expressed in terms of the slope (and its standard error), which corresponded to the change in retinoid concentration for a unit increase in SAA or TNF-α, respectively.

Mastitis study. The sampling period was grouped into 3 time periods: the preinfection period comprising d −7, −4, −1, and 0; the acute-phase period comprising d 0, at 6, 12, and 18 h p.i., and d +1; and the convalescence period comprising d +2, +3, +6, +9, and +13. A mixed model of SAS (version 8) was fitted to the retinoid concentrations and protein concentrations, respectively, with period (3 levels: preinfection, acute phase, and convalescence) as the fixed effect and cow as the random effect. The association between the retinoid and protein concentration was expressed in terms of the slope (and its standard error), which corresponded to the change in retinoid concentration for a unit increase in protein concentration. A significant relationship corresponded to a slope being significantly different from 0. Finally, the effect of retinoid concentrations in the acute-phase period on the reduction in milk production (related to mastitis severity) was studied by a fixed effect model.

RESULTS

Partus Study

Retinoid concentrations during the peripartum period. Throughout the partus study period, ROH and 2 retinoic acid isomer metabolites (atRA, 13cisRA) were detected in all samples at a sufficient level for quantification. The 9-cis isomer was present in all samples, but
VITAMIN A DURING PERIPARTUM PERIOD AND MASTITIS 983

Figure 1. Serum retinol (ROH), serum amyloid A (SAA), and tumor necrosis factor α (TNF-α) concentrations during the peripartum period. Data are means ± SE of 8 cows.

it remained below the limit of quantification (i.e., 3 ng/mL). In all animals, serum ROH concentrations changed significantly (P < 0.0001) with time over parturition. Retinol values reached their minimal value on d 1 or d 2 after calving, started to reestablish by d 3 postpartum, and normalized within 1 wk (Figure 1). No significant fluctuations were observed in the concentrations of atRA and 13cisRA during the peripartum period.

SAA and TNF-α concentrations during the peripartum period. Parturition induced a significant increase in SAA concentration (P < 0.0001). Maximal values were detected in the immediate peripartum period and returned to baseline values within 1 wk after parturition. Fluctuations were observed in the concentrations of TNF-α during the peripartum period, although no significant differences were detected (Figure 1).

Relation between retinoid and SAA or TNF-α concentrations. A significant linear relationship existed between SAA and serum ROH concentrations with each unit increase in SAA concentration (1 mg/L) leading to a decrease of 1.41 ng/mL of ROH (slope = -1.41, SE = 0.123, and P < 0.0001). There was no significant association between serum ROH and TNF-α concentrations during the peripartum period.

Mastitis Study

Characteristics of heifers with acute E. coli mastitis. Following intramammary E. coli infusion, all 6 heifers became ill, suffering from acute coliform mastitis. Clinical signs of inflammation (i.e., rubor, tumor, calor, dolor, and functio laesa) were present at the infection site. Furthermore, animals showed moderate signs of systemic disease and all cured spontaneously (Figure 2). The number of circulating leukocytes decreased during the acute-phase reaction. This initial leukopenia (6, 12, and 18 h p.i.) was counteracted by a leukocytosis lasting until 6 d p.i., whereafter total blood leukocyte counts returned to preinfection values. Milk SCC increased spectacularly at 6 h p.i., remaining high during the convalescence period. The number of colony-forming units of E. coli in the infected quarters was elevated at 6 h p.i., where after the number of colony-forming units gradually decreased. Rectal temperature peaked at 6 h p.i. (40.07 ± 0.13°C), was still elevated at 12 h p.i., and normalized at 18 h p.i. The mean SAA concentration in the acute-phase period was 10-fold higher than during the preinfection period. The maximal concentration of SAA was reached at d 1 p.i. During the convalescence period, mean SAA decreased, but it was still elevated compared with the preinfection value. Mean albumin concentration decreased significantly during the acute-phase period, with the lowest concentration to be found at 12 h p.i. Concentrations of albumin normalized during convalescence (Table 1).

Retinoid concentrations during E. coli mastitis. Throughout the mastitis study period, ROH and 2 retinoic acid isomer metabolites (atRA and 13cisRA) were detected in all samples at a sufficient level for quantification (Table 1, Figure 3). The 9-cis isomer was present in all samples, but it remained below the limit of quantification. Serum ROH concentrations started to decrease
Table 1. Serum amyloid A (SAA), albumin, and serum retinoid concentrations during 3 time periods of acute coliform mastitis in heifers. Preinfection period comprised d −7, −4, −1, and 0; the acute-phase period comprised d 0, at 6, 12, and 18 h p.i., and d +1; and the convalescence period comprised d +2, +3, +6, +9, and +13. Results are means (SE) of 6 animals.

DISCUSSION

Serum concentrations of vitamin A derivatives were determined during the peripartum period (2 d before until 7 d after parturition) and during experimentally induced E. coli mastitis (from 7 d before challenge to 13 d p.i.). In addition to the classical ROH determination, the chromatographic set-up (Van Merris et al., 2002) allowed the simultaneous quantification of 3 retinoic acid isomers in bovine serum.

We were able to confirm the important decline in serum ROH concentrations in the immediate postpartum period, as previously described in dairy cows by Johnston and Chew (1984) and Goff and Stabel (1990). Colostrum production accounts for the major portion of the decline in ROH after parturition, as demonstrated in a recent mastectomy study (Goff et al., 2002). We detected atRA and slightly higher 13cisRA concentrations in bovine serum during the periparturient period;
the 9-cis isomer remained below the quantification limit. In analogy with Goff et al. (2002), concentrations of the acid metabolites atRA and 13cisRA were not affected by parturition in heifers. Although large variations were observed in the concentrations of serum TNF-α, no uniform pattern with regard to parturition was detected. This is in accordance with data of Koets et al. (1998), but it is in contradiction with the in vitro study of Sordillo et al. (1995). The acute-phase protein SAA increased during the immediate postpartum period. It has been suggested that the synthesis and release of this protein is a consequence of normal uterine involution, endometrial degeneration, and tissue remodeling (Koets et al., 1998).

Experimentally induced coliform mastitis in dairy cows during early lactation caused sepsis, a systemic inflammatory response to an active infectious process (Bone et al., 1992). All heifers suffered from general illness, with clinical signs of quarter inflammation and moderate systemic symptoms. The presence of an acute-phase response was documented by fever, initial leukocytosis, increase in SAA, and decrease of albumin in circulation. Interestingly, the acute-phase response was accompanied by a significant decrease in serum ROH during experimentally induced mastitis. This phenomenon is in accordance to the well-described acute phase-related hyporetinemia in humans (Beisel, 1998; Mitra et al., 1998; Schweigert, 2001) and rats (Rosales and Ross, 1998). Moreover, a significant increase of atRA and a decrease of 13cisRA were detected at the same timepoint as the minimal concentration of serum albumin.

The mechanism underlying the acute phase-related decrease in ROH is not yet fully elucidated, but a number of possibilities have been proposed (Schweigert, 2001; Stephensen, 2001): decreased mobilization and transport of ROH from the liver, excretion of ROH in the urine, and increased metabolic requirements. Assuming that the observed changes in ROH serum concentrations reflect an increased requirement, it is tempting to speculate on increased utilization of retinoids during infection. The most intensively discussed possibility is the consumption of circulating antioxidants during neutralization of free radicals caused by activation of neutrophils (Sies and Stahl, 1995).

The transient changes in retinoic acid isomers (the metabolically active forms of vitamin A) observed in the current study during acute coliform mastitis are remarkable and have not been previously described in literature. During the acute-phase reaction, the increase of atRA is largely mirrored by a lowering of 13cisRA. Retinoic acid signals are mediated by specific nuclear receptors, the retinoic acid receptors and retinoid X receptors, which are part of a complex signaling network, allowing for receptor-receptor and receptor-DNA interaction (Petcovich et al., 1987). Because 13cisRA does not display a strong binding affinity for these retinoid receptors, it is believed that 13cisRA can act by serving as a precursor for the more transcriptionally active atRA (Blaner, 2001). Steric isomerization of 13cisRA to atRA, catalyzed by an isomerase, may thus be of importance to nuclear retinoid receptor-mediated biological activities. The different retinoic acid isomers have been shown to be enzymatically interconverted in a reversible way in vivo (Kojima et al., 1994).

Alternatively, the increase in atRA during the acute-phase reaction can partially be attributed to substantial increases in the oxidation of ROH to atRA. A mechanism for this hypothesis can be provided by the knowledge of the metabolic steps catalyzed by retinoid dehydrogenases during conversion of ROH to retinoic acid. The first and rate-limiting step involves the reversible conversion of ROH into retinal by alcohol dehydrogenases; retinal is then irreversibly oxidized into atRA by NADP+-dependent aldehyde dehydrogenase(s) (Duester, 2000). Regulation of retinoic acid biosynthesis has not been fully elucidated, although prostaglandins may be modulatory at the site of conversion (Napoli, 1993). Nonetheless, our data strongly indicate a transient bioactivation mechanism (Chen and Juchao, 1998), possibly involving significant modifications in the activity of these dehydrogenases and putative isomerase during the acute-phase reaction. Some enzymes from the dehydrogenase families specialized in retinoid metabolism are known to be genetically highly conserved (Duester, 2000). Extrapolation of the present data, obtained during acute coliform mastitis in heifers, to other animal or human models seems therefore justified, although it can not be excluded that species-specific enzymes might also have contributed to our findings.

Whereas the reduction in serum ROH may reflect increases in general consumptive or oxidative processes, there is no clear evidence to suggest that the reduction has any relationship with the outcome of the animal (Schweigert, 2001), whereas such an association was found for serum 13cisRA concentrations. The changes in serum retinoid levels may either have an important causal relationship with the outcome or may simply represent secondary phenomena. The former suggestion would provide a strong argument for the supplementation of vitamin A in dairy cows during the peripartum period, as it may reduce the incidence and severity of mammary infections (Chew et al., 1982; Johnston and Chew, 1984; Oldham et al., 1991).

The transient and self-correcting nature of the changes in vitamin A concentrations during coliform mastitis in heifers argues against a true deficiency state.
and indicates that acute infection influences the retinoid metabolism in far more complex ways than the simple depletion of vitamin A stores. In humans, it has previously been suggested that the serum ROH concentration that is reached during the acute phase of infection is due primarily to transient changes in vitamin A metabolism unrelated to total liver stores (Mitra et al., 1998). Furthermore, proportionately similar reductions in serum ROH in response to endotoxin were found in vitamin A-deficient and vitamin A-adequate rats (Rosales and Ross, 1998), indicating that the effect of inflammation on ROH concentration does not depend on vitamin A status.

CONCLUSIONS

In summary, this paper confirms the hyporetinemia observed in dairy cows during the immediate postpartum period. Furthermore, it describes the vitamin A profile during the acute-phase reaction of infection, using an E. coli-induced mastitis in heifers during early lactation. The cow model used in the study apparently reproduced the marked but transient reduction in serum ROH, as observed during infection in humans and rats. In addition, atRA was shown to be the most abundant retinoic acid isomer during the acute-phase reaction of mastitis in bovine, providing evidence of a shift in retinoid metabolism towards the active metabolite. Although interactions between retinoids and important immune response factors such as immune cells, adhesion molecules, and cytokines have been postulated (Semba, 1998), the functional importance of the infection-induced changes in serum retinoid levels awaits further clarification. The present data show the involvement of atRA in the acute phase-related hyporetinemia and form a strong indication for the key role of atRA in modulating the immune response during infection.
