Effects of Dietary Vitamin C on Neutrophil Function and Responses to Intramammary Infusion of Lipopolysaccharide in Periparturient Dairy Cows

W. P. Weiss¹ and J. S. Hogan
Department of Animal Sciences, Ohio Agricultural Research and Development Center, The Ohio State University, Wooster 44691

ABSTRACT

Neutrophil function and the severity and incidence of mastitis in dairy cows is related to the intake of many antioxidant nutrients. Because vitamin C is the major water-soluble antioxidant in mammals, we examined the effect of dietary vitamin C on neutrophil function and responses to intramammary infusion of lipopolysaccharide (LPS) in periparturient dairy cows. At 2 wk before anticipated calving, Holstein cows were fed diets that provided 0 (16 cows) or 30 (15 cows) g/d of supplemental vitamin C (phosphorylated ascorbic acid). Treatments continued until 7 d after cows received an infusion of 10 μg of LPS into one quarter of the mammary gland (on average, this occurred 32 d postcalving). Supplementation of vitamin C increased plasma concentrations of vitamin C at calving, but no differences were observed in samples taken 24 h postinfusion. Concentrations of vitamin C in milk (24 h postinfusion) and in neutrophils (calving and 24 h postinfusion) were not affected by treatment, but vitamin C concentrations in neutrophils isolated from milk were about 3 times greater than concentrations in blood neutrophils. The LPS infusion did not alter concentrations of vitamin C in plasma or milk, suggesting that the LPS model did not produce the same effects as a bacterial infection of the mammary gland with respect to antioxidant effects. Supplemental vitamin C had no effect on neutrophil phagocytosis or bacterial kill. Dietary vitamin C reduced the milk somatic cell count but did not affect the febrile response or milk production following LPS infusion.

Key words: antioxidant, mastitis, neutrophil, vitamin C

INTRODUCTION

A clear link exists between the proper supplementation of many nutrients (e.g., Cu, Se, vitamin E) involved in antioxidant systems of cows and the severity and incidence of mastitis (Smith et al., 1984; Erskine et al., 1989; Weiss et al., 1997; Scaletti et al., 2003). Ascorbic acid is the most abundant and probably most important water-soluble antioxidant in mammals (Sauberlich, 1994). Even though cows can synthesize vitamin C and vitamin C is not a required nutrient for dairy cows, data are accumulating that suggest vitamin C is related to mastitis. Cows with mastitis have lower concentrations of vitamin C in the plasma and milk (Weiss et al., 2004; Kleczkowski et al., 2005) and the severity of clinical signs is correlated with the magnitude of the decrease in concentrations (Weiss et al., 2004). Subcutaneously injected vitamin C may have therapeutic value for cows with mastitis (Naresh et al., 2002; Ranjan et al., 2005); however, the methodologies used in previous studies have produced equivocal results. The severity of some clinical signs were reduced when cows were injected with vitamin C following an intramammary infusion of LPS (Chaiyotwittayakun et al., 2002). Intracellular concentrations of ascorbic acid increase dramatically when human neutrophils are activated (Washko et al., 1993), perhaps to protect the cells and surrounding tissues from damage caused by reactive oxygen species (ROS) generated by the oxidative burst of the neutrophils. This may be one explanation for the link between vitamin C and mastitis. The effects of dietary supplementation of vitamin C on mastitis and neutrophil function of dairy cows are not known.

We hypothesized that feeding a form of vitamin C that has been shown to increase plasma concentrations of vitamin C in dairy cows would improve neutrophil function via its antioxidant properties and would lessen the severity of LPS-induced mastitis. Because antioxidant status appears to be compromised in the peripartum period (Goff and Stabel, 1990; Weiss et al., 1990) the experiment was conducted with peripartum cows. The objectives of this experiment were to determine whether 1) LPS-induced mastitis reduced milk and plasma concentrations of vitamin C; 2) supplemental dietary vitamin C affected concentrations of vitamin C in blood and milk neutrophils; and 3) supplemental dietary vitamin C during the peripartum period im-
proved neutrophil function and reduced the severity of clinical signs following an LPS infusion into the mammary gland.

MATERIALS AND METHODS

Cows and Treatments

At 60 d before anticipated calving, dry Holstein cows and heifers were moved to a common free-stall pen and fed a diet formulated to meet the requirements of dry cows (NRC, 2001). Animals (n = 34) were blocked based on parity (cows or heifers) and expected calving date into groups of 2 (11 blocks of cows and 6 blocks of heifers were assigned to the experiment). At 2 wk before anticipated calving, animals were moved to individual box stalls and DMI was measured starting at d 1 postcalving until 7 d after the mammary gland infusion of LPS (average 39 d postcalving).

Blood Sampling

Blood samples were taken via the tail vein into tubes containing heparin and into tubes containing EDTA (10 and 50 mL of blood, respectively) on 1) 1 to 3 d before cows were moved to box stalls [averaging 13 d (SD = 5.7) before actual calving], 2) the first full Thursday following calving (averaging 4 d after calving, SD = 1.9), and 3) 24 h after cows received the mammary gland infusion of LPS (averaging 32 d after calving, SD = 9.4). Within 30 min of collection, tubes containing heparinized blood were centrifuged (1,000 × g at 4°C for 15 min) and the plasma was used for vitamin C analysis. Neutrophils were isolated from the blood samples containing EDTA (Hogan et al. (1992)).

Neutrophil Function

Neutrophil phagocytosis and intracellular kill of Escherichia coli 487 (originally isolated from a clinical case of bovine mastitis) were determined in blood neutrophils isolated from the calving sample. Phagocytosis and intracellular kill of bacteria by neutrophils were measured by modifications of the fluorochrome assay described by Goldner et al. (1983). Neutrophils were collected and bacteria prepared as described by Hogan et al. (1992). Briefly, bacteria were cultured to the stationary phase of growth, washed, and opsonized in 10% heat-inactivated serum for 20 min. Suspensions of neutrophils and opsonized bacteria were added to incubation tubes in a ratio of 1:2 (neutrophils:bacterial colony-forming units) and incubated at 100 rpm for 90 min. The phagocytic index was calculated as the average number of bacteria phagocytosed per neutrophil. Intracellular kill was determined as [number of dead phagocytosed bacteria/number of live + number of dead intracellular bacteria] × 100. The percentage of neutrophils phagocytizing was calculated as the number of neutrophils with at least one intracellular bacteria divided by the total number of neutrophils × 100. All assays were in duplicate and conducted blind relative to laboratory personnel having prior knowledge of cow or treatment.

LPS Infusion

At an average of 32 d postcalving (SD = 9), either the right or left front mammary quarter from each cow was

1Mineral mix for prepartum diet: 13% dicalcium phosphate, 27% limestone, 15% magnesium oxide, 12% magnesium sulfate, and 33% trace mineral salt. For lactation diet: 25% dicalcium phosphate, 45% limestone, 6% magnesium oxide, 32% trace mineral salt, and 17% sodium bicarbonate.

2For prepartum diet, mix provided (per kg of diet DM): 86 IU of vitamin E/kg, 1,940 IU of vitamin D, 8,940 IU of vitamin A, 12 mg of Cu (from copper sulfate), 0.3 mg of Se (sodium selenate), and 37 mg of Zn (zinc sulfate). For lactation diet, mix provided (per kg of diet DM): 4,260 IU of vitamin A, 1,160 IU of vitamin D, 25 IU of vitamin E/kg, 9 mg of Cu (from copper sulfate), 0.3 mg of Se (sodium selenate), and 89 mg of Zn (zinc sulfate).
infused with LPS via the teat canal. Infusions were 3 h after the morning milking (0200), and only uninfected quarters were infused. Infection status was determined by microbiological culture of samples taken 7, 2, and 1 d prior to infusions. Concentrated LPS was purchased (E. coli O26:B6; Sigma Chemical Co., St. Louis, MO), diluted in PBS, and sterilized by passage through 0.2-μm pore filters. The challenge inoculum was 10 μg of LPS in 10 mL of PBS. Milk samples were collected from infused and noninfused quarters at 2, 4, 6, 8, 10, 12, 24, 48, 72, and 96 h after infusion to determine the speed and magnitude of intramammary neutrophil response. The SCC per milliliter of milk was determined by a Bentley Somatocount 150 milk somatic cell counter (Bentley Instruments, Inc., Chaska, MN). Samples from clinical quarters were diluted 1:10 and 1:50 (Bentley Instruments, Inc., Chaska, MN). Samples were assayed for total vitamin C using the same HPLC procedure as used for plasma. Blood neutrophils collected on −10 d, calving, and 24 h postinfusion, and milk neutrophils collected 24 h postinfusion were assayed for total vitamin C.

**Statistical Analyses**

Of the 34 animals assigned to the experiment, data from 3 cows were not used (2 cows on the vitamin C treatment and 1 control). One cow (vitamin C treatment) calved 9 d before expected and therefore received the treatment on only 1 d, 1 cow (control) had severe metritis, and 1 cow (vitamin C) had several metabolic disorders shortly after calving. Production and neutrophil function data were analyzed with PROC MIXED (SAS Institute, 2004). The model included block (random), treatment (fixed), and error. Repeated-measures data (vitamin C concentrations in plasma and blood neutrophils, and SCC, body temperature, and milk production during the LPS infusion experiment) were analyzed with PROC MIXED. The model included block (random), treatment (fixed), time (repeated, fixed), treatment by time interaction (fixed), and error. The analyses for vitamin C concentrations in plasma and blood neutrophils were conducted with and without (before treatment began) the precalving values. The SLICE option was used to compare treatment means within each time point and to compare time means within each treatment. Vitamin C concentrations in blood neutrophils were compared with those in milk neutrophils using a model that included block (random), dietary treatment (fixed), source of neutrophil (repeated within cow and fixed), treatment by source interaction, and error. The same model was used to compare concentrations of vitamin C in milk from the quarter that received LPS to a composite sample from the 3 quarters that were not infused (source of milk replaced the source of neutrophils).

**RESULTS AND DISCUSSION**

Milk production and DMI were not affected by treatment. During the lactation period (calving until the day before the mammary gland infusion), milk production averaged 39.6 and 38.5 kg/d (SEM = 1.5; P > 0.5) and DMI averaged 18.8 and 19.1 (SEM = 0.5; P > 0.5) for control and vitamin C-supplemented cows, respectively (data not shown).
The time effect also would include any effect of the LPS infusion. We anticipated that plasma vitamin C concentrations would decrease following the LPS infusion, because cows that have either a natural (Klekzowski et al., 2005) or experimentally given (Weiss et al., 2004) bacterial infection of the mammary gland have substantially (40 to 50%) lower concentrations of vitamin C in plasma than cows that are not infected. Because we did not collect a sample immediately before infusion, we cannot unequivocally state that the LPS infusion did not decrease plasma vitamin C. However, the time profile of plasma vitamin C concentrations (Figure 1) essentially mirrors that of a previous study (Padilla et al., 2005) in which early-lactation cows were not infused with LPS and did not have mastitis. One possible reason the plasma concentration of vitamin C did not decrease following LPS infusion is that the severity of the inflammatory response was less than that observed with a bacterial infection. The body temperature and milk production responses (discussed below) were mild compared with clinical responses following an _E. coli_ infection (Weiss et al., 2004). Kleczkowski et al. (2005), however, reported lower plasma concentrations of vitamin C in cows that had bacterial infections of the mammary gland but had normal body temperature and no gross clinical signs of illness. Another possible reason for the different results between this study and previous work is that a 10-μg infusion of LPS caused different responses than a bacterial infection. A likely reason for the decrease in vitamin C concentrations during a bacterial infection of the mammary gland is that vitamin C is destroyed by ROS that are produced by the oxidative burst of neutrophils during phagocytosis and bacterial kill. Intramammary infusion with LPS (25 μg) causes increased production of ROS by milk neutrophils (Mehrzad et al., 2001), but the production of ROS induced by a 10-μg infusion of LPS may have been substantially less than when a bacterial infection is present.

**Effect of Vitamin C Supplementation.** Cows fed supplemental vitamin C had greater (_P_ < 0.06) concentrations of vitamin C in plasma sampled 4 d after calving but not (_P_ > 0.55) in samples collected 24 h after the LPS infusion (Table 2). At 4 d postcalving, plasma vitamin C concentrations were about 17% greater in cows fed supplemental vitamin C than in the control cows. Midlactation dairy cows fed the same form and amount of supplemental vitamin C for 28 d had plasma vitamin C concentrations that were 25% greater than the controls (Weiss, 2001). The reasons supplemental vitamin C did not affect concentrations of vitamin C in plasma before calving are not known. One possibility is that vitamin C, a major water-soluble antioxidant, differs from vitamin E, a major lipid-soluble antioxidant, because plasma concentrations of α-tocopherol are markedly reduced in the peripartum period (Goff and Stabel, 1990). If plasma concentrations are an indicator of vitamin C status, parturition does not appear to negatively affect vitamin C status.

Vitamin C Concentrations in Neutrophils

Blood Neutrophils. The concentrations of vitamin C in blood neutrophils were not affected \( (P > 0.5) \) by treatment at any time point (Table 2). The lack of an effect of supplementation agrees with previous work conducted on dairy heifers (Macleod et al., 1999a). Time affected \( (P < 0.05) \) concentrations in neutrophils in both control and supplemented cows. This effect was caused by the lower concentrations observed in the samples collected before calving. There are several possible reasons why vitamin C concentrations in blood neutrophils were higher after calving than before calving. In isolated human blood neutrophils, the concentration of intracellular ascorbic acid increased linearly as the concentration of ascorbic acid in the incubation media increased from 5 to 15 mM (Washko et al., 1989). The trend toward increased concentrations of plasma vitamin C as cows progressed from late gestation to early lactation could have contributed to increased concentrations of vitamin C in neutrophils (the correlation between concentrations of vitamin C in plasma and blood neutrophils was 0.28, \( P < 0.01) \). Glucose at physiological concentrations reversibly inhibits uptake of ascorbic acid by human neutrophils (Washko and Levine, 1992). Late-gestation cows typically have higher concentrations of plasma glucose than early lactation cows (Studer et al., 1993), and this possibly could have contributed to the lower concentrations of vitamin C observed in late gestation compared with postpartum concentrations.

Milk Neutrophils. Supplementation of vitamin C did not affect \( (P > 0.25) \) vitamin C concentrations in neutrophils isolated from milk from the quarter infused with LPS (Figure 2). Milk neutrophils, however, had about 3 times greater \( (P < 0.01) \) concentrations of vitamin C than did neutrophils isolated from blood collected at the same time (Figure 2). When human neutrophils are activated, ascorbic acid is actively taken up and intracellular concentrations increase 10- to 30-fold compared with resting neutrophils (Washko et al., 1993; Wang et al., 1997). The increased uptake of ascorbic acid by activated neutrophils is likely a defense mecha-
Figure 2. Effect of feeding 0 (open bars) or 30 g/d of supplemental vitamin C (solid bars) on concentrations of vitamin C in polymorphonuclear neutrophils (PMN) isolated from milk (infused quarter) or blood. Samples were taken 24 h after intramammary infusion of LPS into one quarter. Vitamin C treatment had no effect \((P > 0.5)\), but concentrations were greater \((P < 0.01)\) in milk neutrophils than in blood neutrophils. Error bars indicate SE.

The LPS infusion resulted in an influx of somatic cells (discussed below) into the infused quarter. During diapedesis, neutrophils become activated; therefore, the 3- to 4-fold difference in vitamin C concentrations between milk and blood neutrophils possibly was caused by activation.

**Milk.** The concentrations of ascorbic acid, DHAA, and vitamin C in milk taken 24 h after LPS infusion were not affected \((P > 0.20)\) by dietary treatment (Table 3). Concentrations of those compounds also did not differ between milk collected from the quarter infused with LPS and milk collected from the healthy glands. The measured concentrations and the lack of an effect of supplemental dietary vitamin C were consistent with previous work (Weiss, 2001). However, the similar concentrations in milk from the infused quarter and healthy quarters was not expected. The concentration of vitamin C in milk from a quarter infused with *E. coli* was about 50% lower than milk from the quarters not infused (Weiss et al., 2004). Milk from cows with natural bacterial infection in at least one quarter had lower concentrations of vitamin C than did cows with no bacterial infection (Reineke et al., 1941). We also expected that the proportion of vitamin C that was DHAA would increase in the infused quarter (Weiss et al., 2004), but we actually observed a trend \((P < 0.10)\) toward a lower proportion of DHAA in milk from the infused quarter (Table 3). As with plasma concentrations, the lack of a difference between vitamin C concentrations in milk from healthy quarters and LPS-infused quarters may have been caused by the experimental model. If production of ROS in the mammary gland was less with the dose of LPS used in this experiment compared with bacterial infection, the reduction in vitamin C concentrations would also be less.

**Neutrophil Function**

Treatment did not affect the function of neutrophils isolated from blood samples taken at calving (Table 4),

\(^1\)Positive neutrophils contained at least one bacterium (*Escherichia coli* 487). Intracellular bacteria/neutrophil is the average number of bacteria in neutrophils that contained at least one bacterium. The phagocytic index was calculated by multiplying intracellular bacteria/neutrophil by (positive neutrophils/100). Intracellular kill was determined as number of dead, phagocytized bacteria/(number of live + number of dead intracellular bacteria) \(\times\) 100. Treatment did not affect any measure \((P > 0.25)\).
similar to the lack of a treatment effect on vitamin C concentrations in neutrophils (Table 2). A subcutaneous injection (1 d before blood was sampled) of ascorbic acid (20 mg/kg of BW) given to steers enhanced the neutrophil kill of *Staphylococcus aureus* (Roth and Kaeberle, 1985). Phagocytosis of latex particles by human neutrophils was enhanced when the cells were incubated in media containing ascorbic acid (Bergman et al., 2004). One possible reason for the different results is that the concentrations of ascorbic acid to which the neutrophils were exposed were likely much greater in the cited studies than in the current study. The concentration of vitamin C in plasma at calving was approximately 25 μM, but in the in vitro study, cells were incubated in media containing approximately 1 mM. Plasma concentrations of vitamin C were not measured in the steer study (Roth and Kaeberle, 1985), but plasma ascorbic acid concentrations increased to approximately 450 μM after dairy cows were given a single injection of ascorbic acid of approximately 40 mg/kg of BW (Chaiyotwittayakun et al., 2002).

**Clinical Responses to LPS Infusion**

The intramammary infusion of LPS produced a mild inflammatory response. Body temperature peaked 12 h postinfusion at approximately 39°C (less than 0.5°C above basal) and returned to normal by 24 h postinfusion (Figure 3). Treatment did not affect the febrile response. The SCC response was affected by time (P < 0.01), treatment (P < 0.01), and a time by treatment interaction (P < 0.05). Peak SCC occurred at 12 h for
both treatments, but the SCC was lower \((P < 0.01 \text{ to } P < 0.05)\) at 4, 6, 8, 10, 12, and 24 h postinfusion for cows fed supplemental vitamin C than for control cows (Figure 3). Daily DMI was not affected \((P > 0.20)\) by treatment and no decrease was evident postinfusion (data not shown). Dry matter intake for all cows averaged 20.9 kg/d for the 3 d before infusion, 20.9 kg/d for the day of infusion, and 21.9 kg/d for the 3 d postinfusion. Milk production during the infusion experiment was not affected by treatment but was reduced \((P < 0.05)\) by the infusion (data not shown). Average milk production for the day before, the day cows were infused, and after infusion averaged 20.9 kg/d for the 3 d before infusion, 20.9 kg/d for the day cows were infused, and the following day was 43.7 (SEM = 1.5), 40.5 (SEM = 1.2), and 43.2 (SEM = 1.2) kg/d, respectively. The depression in milk production lasted only 24 h and averaged 7% compared with yields on the days before and after infusion.

In a previous experiment that also used LPS (Chaiyotwittayakun et al., 2002), intravenous administration of ascorbic acid after LPS infusion (25 g at 3 and 5 h postinfusion) did not affect the febrile response or SCC but did attenuate the reduction in milk yield following LPS. In that experiment, 100 \(\mu g\) of LPS was used, and body temperature and SCC spikes were lower (approximately 41°C and 1x10^7) and loss in milk was greater (approximately 22%) than in our study. The use of 10 \(\mu\)g of LPS as an intramammary challenge simulates the clinical response typically seen in a mild clinical case of coliform mastitis (Barrett et al., 1997). One advantage of using a nonreplicating intramammary irritant such as LPS to measure the SCC response, compared with a live bacterial challenge, is that the LPS is delivered in a finite amount and the SCC response will not be confounded by the replication rate of bacteria because of noncellular growth factors in lacteal secretion. The speed of the SCC response was comparable between treatment groups following LPS infusion in the current trial; however, the number of cells recruited into the gland in response to the same amount of LPS was greater for nonsupplemented cows. The number of neutrophils entering the mammary gland depends on the amount of irritant (Paape et al., 1979), and excessive influx may relate to mammary damage because proteases released by neutrophils appear to be actively involved in udder tissue damage during mastitis (Mehrzad et al., 2005).
