ABSTRACT

The underlying molecular mechanisms that control milk yield and milk protein yield in domestic animals are not completely understood. In this study, the galactopoietic response to exogenous growth hormone (GH) was used as an experimental model to investigate the role of translation initiation and elongation in the regulation of milk protein synthesis in the mammary gland. A slow-release formula of commercially available GH was administered via a single subcutaneous injection to 4 lactating cows (GH group). A further 4 cows were given a single subcutaneous injection of saline (control group). Changes in mRNA transcript level and protein phosphorylation status of key members of the mammalian target of rapamycin (mTOR) pathway were assessed in mammary gland tissues of these animals using quantitative real-time PCR and Western blotting. The GH treatment enhanced the phosphorylation of ribosomal protein S6 and increased the protein abundance of eukaryotic initiation factor 4E (eIF4E) and eukaryotic elongation factor 2 (eEF2) proteins in the mammary gland of GH-treated animals. These results indicate a link between milk protein synthesis and the regulation of mRNA translation. The GH treatment did not change mRNA abundance of ribosomal protein S6, eIF4E, and eEF2, nor did it change the mRNA (mTOR, eEF2 kinase) or protein abundance of eEF2 kinase. These results demonstrate that GH administration changes mRNA translation initiation and elongation possibly via the mTOR pathway (suggested by the increased levels of ribosomal protein S6 phosphorylation), indicating that the mTOR pathway might be a potential control point in the regulation of milk protein synthesis in the mammary gland.

Key words: growth hormone, mammary gland, bovine, gene expression

INTRODUCTION

Milk, especially milk protein, is an important source of nutrition for humans and production needs to increase to match global demand (Huffman and Harper, 1999). The composition and yield of milk protein is tightly regulated and varies widely among animals (Jenness, 1979). Growth hormone (GH) has a well-established galactopoietic effect on the bovine mammary gland (Bauman et al., 1985; Molento et al., 2002); however, the molecular mechanisms mediating the effect of GH on protein synthesis in the bovine mammary gland remain largely unknown. Several studies have shown that the positive effects of GH on lactation are related to increases in the proliferation and activity of mammary epithelial cells (Berry et al., 2001; Molento et al., 2002) as a result of either the direct effect of GH on the mammary gland or an indirect effect via increased secretion of IGF-1 (Akers et al., 2000; Allan et al., 2002).

Previous studies have indicated that the regulation of protein translation may be important in regulating milk production (Long et al., 2001b; Toerien and Cant, 2007); however, the importance of translational regulation and the effect on milk protein synthesis during established lactation has not been studied. In many tissues (muscle, liver, adipose tissue) GH influences protein metabolism through changes in the protein translation machinery (Bush et al., 2003), specifically changes in the mammalian target of rapamycin (mTOR) signaling pathway (Hayashi and Proud, 2007). These observations suggest that the mTOR may mediate the effects of GH in the bovine mammary gland.

The GH signaling cascade involves the binding of GH to its receptor, followed by the phosphorylation and activation of janus kinase 2 (JAK2). In turn, JAK2 triggers a cascade of signaling events that involve the insulin receptor substrate (IRS), followed by the phosphoinositide 3-kinase (PI 3-kinase) and protein kinase B (PKB; Souza et al., 1994; Carter-Su et al., 1996; Costoya et al., 1999; Harrington et al., 2005). Similar to GH, IGF-I also acts through an IRS cascade (LeRoith
et al., 1995) and it is likely to account for some of the GH effects in the mammary mTOR signaling (Cui et al., 2003). Protein kinase B directly phosphorylates tuberous sclerosis complex-2 (TSC2) in response to GH treatment inducing the activation of mTOR (Hayashi and Proud, 2007). The activation of the mTOR signaling cascade ultimately affects the cellular protein synthetic machinery through changes in the phosphorylation status of eukaryotic initiation factor 4E (eIF4E) binding protein (4E-BP1), and ribosomal protein S6 kinase (S6K). Dephosphorylation of 4E-BP1 prevents eIF4E from binding eIF4G to form complexes that are competent for cap-dependent mRNA translation. Phosphorylated S6K activates several proteins including eukaryotic elongation factor 2 kinase (eEF2K), eukaryotic initiation factor 4B, and ribosomal protein S6, and therefore affects initiation and elongation stages of mRNA translation. Eukaryotic elongation factor 2 kinase is a specific kinase that phosphorylates the elongation factor 2, which inhibits the elongation phase of protein synthesis (Browne and Proud, 2002). Recently it was reported that GH treatment of bovine mammary epithelial cells in vitro induces phosphorylation of PKB (also termed Akt; Sakamoto et al., 2007). The established linkage between GH activation of PKB and downstream activation of the mTOR pathway (Hayashi and Proud, 2007) further suggests the potential involvement of the mTOR pathway in the regulation of milk protein synthesis in the mammary gland.

Although the role of the translation factors in the overall control of protein synthesis has been studied extensively in many tissues, the role of these factors in the mammary gland has only recently received attention. Phosphorylation of ribosomal protein S6 in the mammary gland has only recently received attention. Phosphorylated ribosomal protein S6 in the mammary gland is greater in lactating cows compared with nonlactating animals (Toerien and Cant, 2007), and eIF4E has been implicated in mammary gland development and the onset of lactation (Long et al., 2001a,b). A close linear relationship has also been reported between the amount of eEF2 (phosphorylation status of eEF2 was not evaluated in this study) in the mammary gland at the end of lactation and the amount of protein and casein output in milk (Christophersen et al., 2002). Collectively these studies suggest that translation initiation and elongation factors could be potential targets for the regulation of milk production and thus potentially milk protein synthesis.

The aim of this study was to establish the role of translation initiation and elongation factors in mediating the effects of GH on milk protein synthesis, specifically the role of the mTOR translational regulatory pathway.

### MATERIALS AND METHODS

#### Animals and Milk Composition

All procedures involving animals were carried out in compliance with the guidelines of the AgResearch Grasslands Animal Ethics Committee (Palmerston North, New Zealand). The trial involved 8 nonpregnant, second-lactation spring-calved Jersey cows (189 ± 11 d postpartum), fed with a diet formulated to exceed requirements for ME and MP and essential amino acids (good-quality pasture balage: 11.5 MJ of ME/kg of DM, 45% DM content, offered at 14 kg/cow per day, plus a concentrate milking cow ration: 11.5 MJ of ME/kg of DM, 90% DM content offered at 3 kg/cow per day). The cows were fed at 0700, 1600, and 2000 h, with fresh water available ad libitum. Cows were housed indoors in separate stalls throughout the experiment and were acclimated to indoor housing and concentrate feeding conditions for 2 wk before the experiment. All cows were milked at 0730 and 1630 h, milk yield was recorded (Table 1), and samples were collected at each milking for measurement of milk composition (Table 1). Milk was analyzed for protein, fat, lactose, and SCC by the milk analysis laboratory of Livestock Improvement Corp. (Hamilton, New Zealand).

A slow-release formula of commercially available GH (Lactatropin, Elanco Animal Health, Bryanston, South Africa) was administered via a single subcutaneous injection to 4 lactating cows (GH group). A further 4 cows were given a single subcutaneous injection of saline (control group). Six days following injection, all animals were killed using an overdose of sodium pentobarbitone (Provet NZ, Auckland, New Zealand). Mammary gland samples from the right hind quarter were collected and snap frozen in liquid nitrogen within 5 min postmortem and stored at −85°C for RNA and protein analyses.

Blood samples for the circulating concentrations of IGF-I in the GH group and control group were taken from each cow before each milking on d 0 and on d

3\textsuperscript{Homo sapiens} sequence; the human mTOR sequence used had >99% homology with bovine.

Quantitative Real-Time PCR

Quantitative real-time PCR (qRT-PCR) analysis was used to quantify the expression of specific genes (Table 2). Complementary DNA was synthesized using Transcriptor First Strand cDNA Synthesis Kit (Roche Diagnostics, Mannheim, Germany). Reverse transcription was performed using 0.6 μg of total RNA and oligo-dT primers according to the manufacturer’s instructions. The PCR conditions were 95°C for 10 min, 40 cycles at 95°C for 15 s, 55°C to 67°C (primer-specific optimal annealing temperature) for 15 s, and 72°C for 20 s. Melting curve analysis was performed by increasing the temperature (1°C/s) from 65 to 95°C with continuous fluorescence acquisition.

Primers for the target genes eEF2, eEF2K, eIF4E, 4E-BP1, and mTOR were designed with Primer 3.0 (Rozen and Skaletsky, 2000) using publicly available sequences. The PCR conditions for all primers were optimized and amplicons were sequenced to confirm identity. Specificities of all reactions were verified by melting curves and electrophoresis on 1% agarose gels. Primers for target genes and 2 reference genes are shown in Table 2.

Threshold cycle (CT) values were obtained in triplicate for each sample on the Light Cycler (Roche Diagnostics) using LightCycler FastStart DNA Master plus SYBR Green I (Roche Diagnostics) according to the manufacturer’s protocol. The mean of 3 replicates was used for the statistical analyses. The efficiencies of PCR for each set of primers were calculated for each
SDS-PAGE and Western Blotting

For Western blotting analysis, 300 mg of frozen tissue from individual animals was lysed in extraction buffer (Kimball et al., 1996). Lysates were centrifuged at 13,000 × g for 10 min to remove debris, and the protein concentrations in the resulting supernatants were determined as described by Bradford (1976). Aliquots of lysate containing equal amounts of protein were used for SDS-PAGE and Western blotting, which were performed as described earlier (Kimball et al., 1996); however, different exposure times were required for different proteins to obtain better results. For total ribosomal protein S6, phospho-S6 (Ser235/236), total 4E-BP1, and total eIF4E, exposure times were between 5 and 10 s. For phospho-4E-BP1 (Thr70), a 5-min exposure was required. A 1-min exposure was used for total eEF2K, phospho-eEF2K (Ser366), total eEF2, and phospho-eEF2 (Thr56). Blots were visualized using the enhanced chemiluminescence method. Immobilon P membranes were purchased from Millipore (Billerica, MA), and enhanced chemiluminescence reagents were purchased from Amersham Biosciences (GE Healthcare, Buckinghamshire, UK). Other chemicals were purchased from Sigma unless otherwise stated. Primary antibodies against total ribosomal protein S6, phospho-S6 (Ser235/236), total 4E-BP1, phospho-4E-BP1 (Thr70), total eEF2K, phospho-eEF2K (Ser366), total eEF2, phospho-eEF2 (Thr56), and total eF4E were purchased from Cell Signaling Technology (Beverly, MA). Horseradish peroxidase-conjugated goat anti-rabbit secondary antibody was obtained from Amersham Biosciences (Piscataway, NJ). Each blot was generated at least 3 times with similar outcomes, and the graphs show the densitometry (mean ± SE for 4 animals/treatment). Triplicate blots were averaged for each cow and then averaged across cows within the treatments. Image/J software (available at rsb.info.nih.gov/ij/) was used for quantification where indicated. In the case of Western blotting, data from a typical blot are shown. All data comparisons were analyzed for statistical significance using t-test. Differences were considered significant at a probability value < 0.05.

RESULTS

Milk Yield, Milk Composition, and Hormone Concentration

Mean daily milk and protein production for all cows before treatment (mean ± SE) was 8.5 ± 1.17 L/cow and 0.47 ± 0.055 kg/cow, respectively. There were significant differences between GH and control groups in milk (Figure 1A) and protein (Figure 1B) yields by d 4 of GH treatment. Six days after treatment, GH had increased milk yield by 42% compared with controls, with corresponding increases in protein, fat, and lactose yields (Table 1). Somatic cell analyses showed that there were no significant differences between treatments and there were no significant differences within each day (data not shown).

The serum concentrations of IGF-1 on d 4 and 6 of GH administration were significantly (P < 0.001) higher for the GH group compared with controls (GH: 928.0 ± 26.6 and 582.0 ± 64.2 ng/mL; control: 196.0 ± 26.6 and 74.0 ± 64.2 ng/mL, respectively), indicating that the dosing and timing protocol for GH treatment was successful.

Effect of GH Treatment on mRNA Abundance

Treatment with GH did not change the mRNA levels of the translation factors studied (Figure 2). Figure 2 illustrates the CT values for each animal (black dots) and the average for each group (line) for visualization. These findings suggest that the effect of GH on mammary gland protein synthesis was not mediated through an effect on the expression (mRNA levels) of genes in the initiation and elongation stages of translation. Therefore, further assessment of the expression of other genes in the translational machinery was not pursued.

Effect of GH Treatment on Total Ribosomal Protein S6 and Phospho-S6

Ribosomal protein S6 has been suggested to play an important role in the translation of ribosomal mRNA sequences. The total protein abundance of ribosomal protein S6 in the mammary gland was not changed in response to GH treatment (percentage of treatment in relation to control: 103 ± 6 vs. 100 ± 15; P = 0.86 for the GH and control groups, respectively; Figure 3). However, the phosphorylation of ribosomal protein S6...
at Ser235/236 was increased by GH treatment (percentage of treatment in relation to control: 278 ± 16 vs. 100 ± 18; P < 0.001, for the GH and control groups, respectively; Figure 3).

**Effect of GH Treatment on Total 4E-BP1, Phospho-4E-BP1, and Total eIF4E**

The nonphosphorylated protein 4E-BP1 negatively regulates eIF4F assembly by sequestering its mRNA cap-binding component eIF4E, whereas hyperphosphorylation abrogates this function (Gingras et al., 1999). The protein abundance of 4E-BP1 in the mammary gland was not affected by GH treatment (percentage of treatment in relation to control: 80 ± 12 vs. 100 ± 5; P = 0.20, for the GH and control groups, respectively; Figure 4). The phosphorylation status of the 4E-BP1 at Thr70 (percentage of treatment in relation to control: 242 ± 60 vs. 100 ± 20; P = 0.08, for the GH and control group, respectively) was also unaffected by GH-treatment (Figure 4). Treatment with GH substantially increased the protein abundance of eIF4E (percentage of treatment in relation to control: 229 ± 18 vs. 100 ± 118, P < 0.01, for the GH and control group, respectively; Figure 4). Because eIF4E is rate-limiting in translation, increased milk protein synthesis in response to GH treatment may have been associated with increased availability of eIF4E.

**Effect of GH on Total and Phospho eEF2 and eEF2K**

To examine the effects of GH on the elongation phase of protein synthesis, the protein abundance of eEF2 and eEF2K and the phosphorylation status of eEF2 at Thr56 and eEF2K at Ser366 were analyzed by immunoblotting. Phosphorylation of eEF2K at Ser366 is rapamycin sensitive, and phosphorylation of this site inactivates eEF2K (Browne and Proud, 2004). The phosphorylation of eEF2 at Thr56 inhibits its activity and consequently decreases the speed of the protein synthetic machinery. The protein abundance and phosphorylation status of eEF2K in the mammary gland were not affected by the GH treatment (Figure 5). In contrast, GH treatment significantly increased the protein abundance of eEF2 (percentage of treatment in relation to control: 180 ± 8 vs. 100 ± 9, P < 0.01, for the GH and control group, respectively) and also caused changes in the phosphorylation status of eEF2 at Thr 56 (percentage of treatment in relation to control: 36 ± 12 vs. 100 ± 19, P = 0.05, for the GH and control group, respectively, Figure 5).

**DISCUSSION**

The findings from the current study provide new evidence of the molecular mechanisms mediating the effects of GH on increasing milk protein synthesis and milk and protein yield in lactating dairy cows observed here and in other studies (Bauman, 1999). As reported in previous short-term studies (Etherton and Bauman, 1998), increased milk production occurred without any change in feed intake (data not shown), supporting the hypothesis that an increased repartitioning of nutrients to the mammary gland or more efficient utilization of nutrients by the mammary gland was implicated in the effect of GH on milk production. The present study provides evidence that the effect of GH on milk production is mediated, at least in part, by upregulating the initiation and elongation phases of protein translation and suggests that mRNA translation step is associated with milk protein synthesis in the lactating cow treated with GH.

Here we show that increased milk protein yield in the GH-treated cows was associated with increased phosphorylation of ribosomal protein S6, suggesting that the effects of GH on lactation may be mediated via the
mTOR pathway. Phosphorylation of ribosomal protein S6 correlates with increased protein synthesis (Jastrzebski et al., 2007) and it was proposed that this effect was via modulation of the uninterrupted stretch of pyrimidine residues (TOP motif) at the 5′ end of the mRNA. The TOP mRNA sequences encode proteins involved in mRNA translation such as translation factors and ribosomal proteins (Kimball, 2002). This would explain the increase in milk protein observed in the GH treated cows in this study. However, different studies (Ruvinsky et al., 2005; Pende, 2006; Ruvinsky and Meyuhas, 2006) have questioned the role of the ribosomal protein S6 in the regulation of 5′ TOP mRNA translation and it is suggested that phosphorylated ribosomal protein S6 is not necessary for 5′ TOP mRNA regulation and it is possible that other mTORC1 target(s) may be responsible for this, which requires further investigation. The potential importance of the mTOR pathway, and notably ribosomal protein S6, on milk protein synthesis in the bovine mammary gland is supported by the observations of Toerien and Cant (2007) in which increased abundance and phosphorylation of ribosomal protein S6 coincided with the onset of lactation.

A key component in the regulation of translation initiation is eIF4E, which is the limiting component of the eIF4F initiation complex. The association of eIF4E with eIF4G is regulated in part by the phosphorylation of 4E-BP1. However, neither the relative abundance of 4E-BP1 nor its phosphorylation was changed (Figure 4) suggesting that the GH effect on milk protein yield is not mediated by a decrease in the formation of the 4E-BP1–eIF4E complex. In contrast, the abundance of eIF4E protein in the mammary gland increased in response to GH treatment (Figure 4) suggesting an increased activation of translation initiation, which may support elevated protein synthesis. The phosphorylation of eIF4E was not measured in this study but warrants further investigation. However, the biological significance of phosphorylation of eIF4E is not completely clear. Minich et al. (1994) suggested that
the phosphorylation of eIF4E enhances its binding to capped RNA, and later reports (Scheper et al., 2002; Slepenkov et al., 2006) showed that phosphorylation actually decreased its affinity for 7-methylguanosine or capped RNA.

We examined the effects of GH on translation elongation by evaluating its effect on eEF2 and its kinase, eEF2K, which is the only kinase identified that phosphorylates eEF2. The activity of eEF2K is controlled via the mTOR pathway as well as by other signaling pathways (Browne and Proud, 2004) in response to insulin and other agents (Proud, 2006). The relative phosphorylation of eEF2K, as well as the total protein abundance of eEF2K did not change in the mammary gland in response to GH (Figure 5). Similarly, the phosphorylation of eEF2 at Thr56 did not change in response to GH treatment, but an increase in the abundance of eEF2 protein was observed in GH-treated cows. A role for eEF2 protein abundance as a rate-limiting factor for milk protein synthesis in the bovine mammary gland is further supported by the observations of Christophersen et al. (2002), who reported that eEF2 levels in mammary gland tissue are 50 times higher than the levels of eEF2 found in muscle, and that there is a close linear relation between the amount of eEF2 in the mammary gland at the end of lactation and the amount of protein and casein output in milk.

The findings from this study show that GH treatment affects both the initiation and elongation stages of translation in the mammary gland of the lactating dairy cow through an increase in the levels of eIF4E and eEF2. Additionally, the effect of GH on the ribosomal protein S6 phosphorylation connects the increase in milk protein production with increased protein synthesis. These proteins are direct downstream targets of mTOR, which has previously been shown to mediate the effects of GH on protein synthesis in hepatic cells (Hayashi and Proud, 2007).
Figure 4. Growth hormone (GH) treatment increased the protein abundance of eukaryotic initiation factor 4E (eIF4E) in the mammary gland but did not affect the phosphorylation of eIF4E binding protein 1 (4E-BP1). The graphs show the phosphorylation of 4E-BP1 (Thr70) normalized for total 4E-BP1 content in the sample and the total eIF4E normalized for total GAPDH content in the sample. In all cases, blots are representative of at least 3 experimental replicates. The 4 lanes for GH (1 to 4) and the 4 lanes for control (5 to 8) represent the 4 animals/treatment used in this experiment. The graph shows the mean ± SE, n = 4/treatment; *P < 0.01.
Figure 5. Growth hormone (GH) treatment changed total eukaryotic elongation factor 2 (eEF2) but did not change the phosphorylation status of eEF2 and eEF2 kinase (eEF2K). Lactating mammary gland lysates from GH-treated and control cows were analyzed by SDS-PAGE and Western blotting using the phospho-specific (Ser366) eEF2K and (Thr56) eEF2. The graph shows the phosphorylation of eEF2K (Ser366) and eEF2 (Thr56) normalized for total eEF2K and total eEF2, respectively. In all cases, blots represent at least 3 experimental replicates. The 4 lanes for GH (1 to 4) and the 4 lanes for control (5 to 8) represent the 4 animals/treatment used in this experiment. The graph shows the mean ± SE, n = 4/treatment; *P < 0.01.
CONCLUSIONS

This study reports for the first time the importance of translation initiation and elongation in the GH-mediated effect on milk protein synthesis in the mammary gland of the dairy cow. Further studies are required to establish whether mTOR mediates the effects on translation initiation and elongation in the lactating mammary gland in response to GH, or whether other pathways are involved.
