Influence of microfiltration and adjunct culture on quality of Domiati cheese

S. Awad,1 N. Ahmed, and M. El Soda
Department of Dairy Science and Technology, Faculty of Agriculture, Alexandria University, Alexandria, Egypt

ABSTRACT

The effects of microfiltration and pasteurization processes on proteolysis, lipolysis, and flavor development in Domiati cheese during 2 mo of pickling were studied. Cultures of starter lactic acid bacteria isolated from Egyptian dairy products were evaluated in experimental Domiati cheese for flavor development capabilities. In the first trial, raw skim milk was microfiltered and then the protein:fat ratio was standardized using pasteurized cream. Pasteurized milk with same protein:fat ratio was also used in the second trial. The chemical composition of cheeses seemed to be affected by milk treatment—microfiltration or pasteurization—rather than by the culture types. The moisture content was higher and the pH was lower in pasteurized milk cheeses than in microfiltered milk cheeses at d 1 of manufacture. Chemical composition of experimental cheeses was within the legal limits for Domiati cheese in Egypt. Proteolysis and lipolysis during cheese pickling were lower in microfiltered milk cheeses compared with pasteurized milk cheeses. Highly significant variations in free amino acids, free fatty acids, and sensory evaluation were found among the cultures used in Domiati cheesemaking. The cheese made using adjunct culture containing Lactobacillus delbrueckii ssp. lactis, Lactobacillus paracasei ssp. paracasei, Lactobacillus casei, Lactobacillus plantarum, and Enterococcus faecium received high scores in flavor acceptability. Cheeses made from microfiltered milk received a higher score in body and texture compared with cheeses made from pasteurized milk.

Key words: Domiati cheese, microfiltration, adjunct culture, pasteurization

INTRODUCTION

Domiati cheese is the major cheese variety in Egypt. It differs from other pickled varieties by the fact that a very high concentration of salt (up to 12%) is added directly to the raw cheese-milk (Abou-Donia, 2007), rather than at the end of the process to the cheese curd. Traditional Domiati cheese had been made from raw milk for a long time; thus, different groups of microorganisms are present in the cheese, some of which participate in flavor and texture development and some of which may be pathogenic or cause defects in cheese (El-Baradei et al., 2007). Pasteurization of milk is recommended before cheese making to improve the hygienic quality of cheese. This has a negative effect on the natural flora present in raw milk and changes some of the physicochemical properties of the milk. Weak curd is obtained when salted pasteurized milk is used in cheese making (Awad et al., 2001).

Microfiltration (MF) constitutes an alternative to heat treatment to reduce the presence of bacteria and improve the microbiological safety of dairy products without modifying the physicochemical properties of milk. Microfiltration is the passage of the product under relatively low pressure (approximately 100 kPa) through a semipermeable membrane with pore sizes ranging from 0.2 to 5 μm (Olesen and Jensen, 1989). As bacteria generally range from 1 to 3 μm, under some circumstances, MF should be able to completely remove bacteria from the fluid permeate. Microfiltration might provide a lower temperature option, and thus, a less-pronounced cooked flavor than pasteurization processing for extended shelf-life dairy products, and no calcium chloride should be added to MF milk for cheese making because MF milk receives a lower load of heat treatment.

Microfiltration has been shown to be effective in reducing the number of bacteria in skim milk (Kelly and Tuohy, 1997). Reduction in total bacteria of 2.8 log (Hoffmann et al., 1996) has been reported for the Bactocatch microfiltration process (Tetra Pak Filtration Systems A/S, Aarhus, Denmark). Microfiltration utilizing a 1.4-μm membrane enables complete removal of somatic cells from skim milk (Giffel and van der Horst, 2004). Olesen and Jensen (1989) found that the initial content of Bacillus cereus spores in milk had a significant effect on the content of spores in MF milk, but that the concentration ratio of milk and circulation pressure had no effects under the conditions studied. McSweeney et al. (1993) found no differences between Cheddar cheese made from pasteurized milk and that made from MF milk. However, Beuvier et al. (1997)
concluded that MF reduced the total amount of bacteria more effectively than pasteurization and that facultative heterofermentative lactobacilli grew more slowly in cheese made from pasteurized milk. The observed sensory differences in the cheeses were attributable to the various treatments. Skeie and Ardo (2000) showed that cheeses made from raw, pasteurized, or MF milk influenced the profiles of free amino acids in a Gouda-type cheese.

Because MF reduces microorganisms more effectively than pasteurization (Kelly and Tuohy, 1997), the lactobacilli associated with good quality cheese are probably also removed. Adjunct cultures are nonstarter lactic acid bacteria, consisting mainly of lactobacilli, which are used in addition to a standard starter to enhance the flavor of cheese (El Soda et al., 2000). Lactic acid bacteria have been isolated from traditional Egyptian dairy products (El-Soda et al., 2003), and the influence of these bacteria on the quality of Ras cheese has been investigated (Awad et al., 2007). Much research has been published to improve the quality of Domiati cheese made from pasteurized milk using selected starter cultures (El-Koussy et al., 1976; Ahmad et al., 1978; Abou-Donia, 1981; Abd-El-Khalek et al., 2008).

The objective of the present work was to study the effect of milk treatment (pasteurization vs. microfiltration) and the addition of starter culture and freeze-shocked adjunct cultures on texture and flavor of Domiati cheese during pickling.

MATERIALS AND METHODS

Starter Cultures

Commercial lactic culture (DVS R704, Chr. Hansen Laboratory, Hørsholm, Denmark), contained Lactococcus lactis ssp. lactis and Lactococcus lactis ssp. cremoris and was used as the starter culture.

Adjunct Culture

Adjunct cultures of Lactobacillus delbrueckii ssp. lactis, Lactobacillus paracasei ssp. paracasei, Lactobacillus plantarum, Lactobacillus rhamnosus, Lactobacillus casei, and 3 strains of Enterococcus faecium were obtained from the collection of Faculty of Agriculture, Alexandria University (El-Soda et al., 2003). Enterococci strains were examined for hemolytic activity before use in cheese making. The adjunct cultures were grown and the cells were harvested, washed, and freeze-shocked as described earlier (Awad et al., 2007). Two mixtures of attenuated strains were used in this study. The first mixture contained L. rhamnosus, L. delbrueckii ssp. lactis, L. plantarum, and 2 E. faecium strains. The second mixture contained L. delbrueckii ssp. lactis, L. paracasei ssp. paracasei, L. casei, L. plantarum, and E. faecium.

The 2 mixtures were adjusted to 1 OD (optical density at 650 nm) in pH 7.0 phosphate buffer (Awad et al., 2007) and used at levels of 0.5, 1.5, or 2 mL/kg of milk.

Commercial adjunct culture (DVS CR401, Chr. Hansen Laboratory) containing L. delbrueckii ssp. lactis, L. paracasei ssp. paracasei, and Lactobacillus helveticus was used at a level of 0.0275 g/kg of milk.

Milk

Raw whole cow and buffalo milks were obtained from the dairy farm at Alexandria University. A mixture of 70:30 of raw cow and buffalo milk (fat: 4.5%; acidity: 0.16 to 0.17% as lactic acid) was used in this study. Raw milk was skimmed (<0.05% fat) in mechanical separator (Alfa-Laval, Tumba, Sweden).

Treatment of Cheese Milk

Pasteurization. The skim milk and cream were pasteurized using a high-temperature short-time technique in a tubular heat exchanger (Actini, Evian, France). The heat treatment used was 74°C and 15 s for skim milk and 78°C and 15 s for cream, followed by quick cooling to 35°C. Pasteurized skim milk was mixed with pasteurized cream to obtain the closest initial level of milk fat (4.4–4.5%).

Microfiltration. Raw skim milk was microfiltered using microfiltration unit (Alfa-Laval) with a ceramic membrane pore size of 1.4 μm, membrane area of 0.2 m², flow rate of 150 L/h per m², and temperature of 50°C. Cold pasteurized skim milk (MF) was mixed with pasteurized cream to obtain the closest initial level of milk fat (4.4–4.5%).

Cheese Making Procedure

Three replicates of experimental Domiati cheeses for each treatment were processed using computer-controlled cheese equipment (INRA, Poligny, France) equipped with four 11-L vats. Seven treatments of Domiati cheeses were made from pasteurized milk and another 7 treatments from MF milk. The 4 vats and these treatments were rotated for each replication to reduce systematic errors. Calcium chloride solution was added at a rate of 0.2 g/kg of pasteurized milk just before adding the starter culture. Starter cultures (DVS R704, 0.15 g/kg) and different doses of freeze-shocked suspensions of adjunct cultures (0.5, 1, or 2 mL/kg) were added individually to milk at 35°C, and DVS CR401 adjunct culture was added at a level of
0.0275 g/kg. The inoculated milk was held for 1 h, and NaCl was added to each vat at level of 12% (wt/wt). A suitable amount of commercial calf rennet was added to coagulate the milk for 90 min. The curd was then transferred to stainless steel molds lined with cheesecloth. After 2 to 3 h, a plate and weights (2–2.5 kg for each 10 kg of cheese milk) were placed to compact the curd. The weights were removed after 4 to 6 h and the cheese mass was divided with a knife into blocks of about 9 × 9 × 9 cm, each weighing 450 to 500 g. The cheese blocks were then arranged in cans that were filled with pasteurized (65°C/30 min) brine (12% salt). The cans were closed and stored at room temperature (20 to 25°C) for 60 d.

**Cheese Composition Analysis**

Total protein was measured by the Kjeldahl method (AOAC, 2000) and fat content by the Gerber method (AOAC, 2000). A Corning flat surface combination electrode was used to measure the pH on the well-mixed ground cheese samples. The moisture content was determined using the moisture analyzer (model HR73, Mettler Toledo, Toledo, OH). Salt content was determined using a chloride meter (Jenway, Dunmow, UK).

**Microbiological Analysis**

Cheese samples (10 g) were homogenized for 4 min with 90 mL of a sterile 2% sodium citrate solution and serially diluted using sterile 0.05% peptone. Appropriate dilutions of milk and sodium citrate solution of cheese were plated on plate count agar for enumerating total microbial count at 32°C for 2 d, violet red bile agar for enumerating coliform bacteria at 37°C for 2 d, potato dextrose agar for the enumeration of yeasts and molds at room temperature (20–25°C) for 5 d, and staphylococci 110 Medium for enumeration of staphylococci at 37°C for 2 d (Difco’s Manual, 1985).

**Assessment of Proteolysis and Lipolysis**

The water-soluble extract (WSE) was prepared by the method developed by Kuchroo and Fox (1982), and free amino acids (FAA) were determined in WSE by using the Cd-ninhydrin method of Folkertsma and Fox (1992) and expressed as millimolar leucine equivalents in WSE by using a standard curve. Free fatty acids were determined by the method of Deeth et al. (1975) and expressed as millimolar equivalents per gram of cheese fat.

**Sensory Evaluation**

Sensory evaluation was carried out at the Department of Dairy Science and Technology, Alexandria University, by a panel consisting of 15 cheese graders, including staff members and assistants, cheese producers, and consumers. Each individual was given 3 blocks (6 × 2 × 2 cm) of cheese per sample. Samples were presented in identical plastic sample cups sealed with plastic lids and identified by a random 3-digit number. The coded samples were randomly presented. The graders were asked to give the cheese an overall grade out of 100, to evaluate whether each sample was typical Domiati cheese, and to provide additional comments. Cheeses were graded at 60 d of age and the following scale was used: 0–25 = unacceptable; 26–50 = poor; 51–75 = acceptable; 76–100 = good.

**Statistical Analysis**

Data reported are the average of 3 measurements. The SAS software package (SAS Institute, 1999) was used for ANOVA. Differences were considered significant at \( P < 0.05 \).

**RESULTS AND DISCUSSION**

**Removal of Bacteria with Microfiltration and Pasteurization**

Across 3 replicates, total bacterial counts of raw skim milk were reduced from 150,000 cfu/mL to 250 and 1 cfu/mL by pasteurization and MF treatments, respectively. Microfiltration achieved an average 5.18 log reductions, and pasteurization of whole milk achieved an average 2.78 log reduction (Table 1). The log reduction in bacterial count caused by MF was comparable to that reported by Maubois (1997). Both coliforms and staphylococci were reduced to undetectable levels by MF and pasteurization.

**Cheese Composition**

Table 2 shows that the Domiati cheeses made from pasteurized milk contained more moisture than cheeses made from MF milk at d 1 of manufacture. The MF milk cheese received a lower load of heat treatment than the pasteurized milk cheese. Minor protein denaturation resulting from pasteurization could explain the higher moisture in cheese from pasteurized milk. Similar results showing the effect of pasteurization and microfiltration of milk on the moisture content of
cheese have been reported by McSweeney et al. (1993) and Skeie et al. (2001).

The moisture in all cheeses significantly decreased during pickling. Most of the moisture losses occurred during the first 30 d of pickling. The cultures used in this study had little or no effect on the moisture content of Domiati cheese. The average moisture content of Domiati cheeses at d 1 of manufacture is comparable to that reported by Awad et al. (2001).

The fat and protein content in cheeses were found to be related to the moisture content in cheeses during pickling. The protein and fat content on a DM basis were not significantly different (P < 0.05) in all cheeses (Table 2). There was a gradual increase in salt in moisture content during the pickling period (Table 2); similar results were reported by Awad et al. (2001).

The gross chemical composition of aged Domiati cheese was in agreement with the typical composition of Domiati cheese (Abd El-Salam and Alichanidis, 2004) and was within the legal limit for Domiati cheese in Egypt (Egyptian Standards, 2000).

### Viability of Total Bacteria in Cheese During Pickling

The total bacterial count was higher in pasteurized milk cheeses than in MF milk cheeses throughout the pickling period (Table 3). The higher bacterial count in pasteurized milk cheese is related to the microbial content of the milk used and the moisture content in cheese (Tables 1 and 2). Total bacterial count can have significant effects on the extent of proteolysis and sensory attributes. Coliform bacteria, staphylococci, yeasts, and molds were not detected in any cheese samples during pickling.

A gradual decline in total bacterial count was seen during pickling in all cheeses, resulting in about a 2.5 log reduction after 2 mo. The results were in agreement with those reported by other authors (El-Koussy et al., 1976; Ahmad et al., 1978; Abou-Donia, 1981; Abd-El-Khalek et al., 2008), which found a decline in the viable bacterial counts during Domiati cheese pickling.

The reduction of total bacterial count during picking of Domiati cheese occurred at a higher rate in cheeses

made from MF milk compared with cheeses made from pasteurized milk (Table 3). The higher reduction rate of viable bacterial count in MF cheeses may be related to the low moisture content in MF cheeses compared with pasteurized milk cheeses.

**Cheese pH During Pickling**

The pH values of experimental cheeses determined during pickling are presented in Table 4. The pH values on d 1 of manufacture of cheeses made using MF milk were higher than those in cheeses made using pasteurized milk. The lower pH values in pasteurized milk cheeses compared with MF cheeses were related to viable bacterial count and moisture content in cheeses (Tables 2 and 3). The pH values of cheeses on d 1 of manufacture were dependent on adjunct culture doses, because the pH value was reduced with increasing culture doses.

The lower pH in cheeses made from pasteurized milk than in cheeses from MF milk is in accordance with the findings of Beuvier et al. (1997). Skeie and Ardo (2000) reported that the total amounts of organic acids, especially of lactic acid, were higher in cheeses made from pasteurized milk than in those made from MF milk.

During cheese ripening, starter and nonstarter lactic acid bacteria continue to produce acids and alkaline proteolytic products (Abd El-Salam and Alichanidis, 2004). pH can be a measure to observe the shifts in the balance between proteolysis and acid production. The pH of all cheeses decreased ($P < 0.05$) gradually throughout the pickling period. During the first week or two, starter bacteria ferment the residual lactose and reduce pH (Choisy et al., 2000). At all pickling times, cheeses made with 2 mL/kg of adjunct culture had significantly ($P \leq 0.05$) lower pH values than the rest of the treatments.

**Proteolysis**

Release of amino acids ($\mu$M leucine equivalents) in WSE of experimental cheeses at different pickling stages is shown in Table 4. The FAA values were higher in cheeses made using pasteurized milk than in cheeses made using MF milk throughout the pickling period. This finding is related to factors such as high moisture content, low pH values, high variable bacterial count, and higher residual chymosin activity. Chymosin activity is also related to high amount of rennet used for coagulation and the high moisture content in pasteurized milk cheeses compared with MF milk cheeses. Free amino acids increased with increasing amounts of added adjunct culture and were higher in cheeses made with adjunct cultures at 2 mL/kg than in cheeses made with 1 mL/kg. Free amino acids increased significantly ($P < 0.05$) as pickling progressed in all cheeses. The major contributors to the production of small peptides and FAA are probably the starter and nonstarter bacterial
enzymes (El Soda et al., 2000). Differences were observed among the cheeses made using different strains and doses of adjunct culture, indicating that the adjunct culture seems to be responsible for the production of FAA in Domiati cheese during ripening. The second mixture of adjunct culture produced a higher level of FAA than first mixture. On the other hand, both mixtures of adjunct cultures isolated from Egyptian dairy products produced more FAA during Domiati cheese pickling than did the DVS adjunct culture. This finding may be related to the proteolytic system of wild lactic acid bacteria used in this study. The production of a high level of FAA in cheese made with added adjunct culture containing E. faecium can be attributed to the high tolerance of enterococci to salt and acid during cheese ripening (Litopoulou-Tzanetaki, 1990; Wessels 1996). Higher values of FAA and FFA were recorded in cheese made using pasteurized milk and using 2 mL/kg of adjunct culture containing mixture 2. These results indicated that adjunct cultures contribute to lipolysis in cheese, and greater lipolysis was found in pasteurized milk cheese than in MF cheeses.

**Sensory Assessment of Cheese**

The mean grades for flavor intensity and body and texture acceptability of cheeses at 60 d of pickling are shown in Table 4. Generally, the pasteurized milk cheeses received higher flavor intensity scores than MF milk cheeses, but both aged cheeses were considered acceptable. High scores for Domiati cheese flavor were noticed on the other hand, both mixtures of adjunct cultures isolated from Egyptian dairy products produced more FAA during Domiati cheese pickling than did the DVS adjunct culture. This finding may be related to the proteolytic system of wild lactic acid bacteria used in this study. The production of a high level of FAA in cheese made with added adjunct culture containing E. faecium can be attributed to the high tolerance of enterococci to salt and acid during cheese ripening (Litopoulou-Tzanetaki, 1990; Wessels et al., 1990) and the production of proteolytic enzymes involved in casein degradation (Bahay-El-Din et al., 2002).

**Lipolysis**

The lipolysis in Domiati cheese during pickling was measured in terms of total FFA (expressed as mM equivalents/g of cheese fat). Free fatty acids increased gradually with increasing pickling period (Table 4). Cheeses made from pasteurized milk showed higher acid values during pickling than cheeses made from MF milk. However, cheeses containing mixture 2 of adjunct cultures exhibited a higher acid value than did those containing mixture 1 and DVS cultures. High acid values in cheeses containing enterococci strains may be attributed to the release of intracellular esterases and lipases (Bahay-El-Din et al., 2002; Giraffa, 2003). Commonly, acid values follow the same trend as soluble nitrogen, suggesting that factors affecting proteolysis may have a similar effect on lipolysis (Kebary et al., 1996). Higher values of FAA and FFA were recorded in cheese made using pasteurized milk and using 2 mL/kg of adjunct culture containing mixture 2. These results indicated that adjunct cultures contribute to lipolysis in cheese, and greater lipolysis was found in pasteurized milk cheese than in MF cheeses.

considerable influence on the cheese flavor (El Soda, 1993; Awad, 2006). In addition, the concentration of FFA, especially short-chain FFA, is responsible for the characteristic cheese flavor (Kanawjia et al., 1995).

Panelists detected differences ($P < 0.05$) in body and texture between pasteurized and MF milk cheeses (Table 4). The MF cheeses received higher scores for overall body and texture than did the pasteurized milk cheeses. The MF cheeses made using 2 mL/kg of adjunct culture containing *L. delbrueckii* ssp. *lactis*, *L. paracasei* ssp. *paracasei*, *L. casei*, *L. plantarum*, and *E. faecium* received the highest overall scores in body and texture acceptability. The main goal of this research was to produce Domiati cheese with high microbiological quality and similar textural and flavor characteristics to its raw milk counterpart. Because the MF milk contained a low level of nonstarter lactic acid bacteria that gave the best results, traditional Domiati cheese flavor did not develop in MF cheese made with a low dose of adjunct culture. On the other hand, pasteurization of milk reduced the body and texture acceptability of Domiati cheese.

**CONCLUSIONS**

It is concluded from the present study that MF milk yielded Domiati cheeses with a lower amount of rennet needed for coagulation, lower bacterial count, lower moisture content, higher pH, slower proteolysis and lipolysis, and increased body and texture acceptability of resultant cheese compared with pasteurized milk. Adding freeze-shocked adjunct cultures of *L. delbrueckii* ssp. *lactis*, *L. paracasei* ssp. *paracasei*, *L. casei*, *L. plantarum*, and *E. faecium* isolated from Egyptian dairy products produced significantly higher amounts of FAA and FFA and contributed to Domiati cheese flavor. Therefore, to obtain a Domiati cheese with typical flavor and texture, it will be of considerable interest to use a combination of MF milk and adjunct cultures. The beneficial role of enterococci in the development of cheese aroma led to inclusion of selected enterococcal strains in certain starter cultures for Domiati cheese. Further work is in progress to establish the possible use of *E. faecium* in commercial starter preparation.
