ABSTRACT

Microbial transglutaminase (MTGase)-induced polymerization of individual milk proteins during incubation was investigated using a proteomics-based approach. The addition of MTGase (0.25–2.0 units/mL) caused the milk proteins to polymerize after a 3-h incubation period. Sodium dodecyl sulfate-PAGE analysis showed that the total intensities of the protein bands that corresponded to αS-casein, β-casein, and κ-casein decreased from 8,245.6, 6,677.2, and 586.6 arbitrary units to 1,911.7, 0.0, and 66.2 arbitrary units, respectively. Components with higher molecular weights were observed, and the intensity of these proteins increased after 3 h of incubation. These results support that inter- or intramolecular crosslinking occurred in the casein proteins of MTGase-treated milk. Two-dimensional electrophoresis analysis indicated that isomers of β-casein, κ-casein, a fraction of serum albumin, αS1-casein, αS2-casein, β-lactoglobulin, and α-lactalbumin in the milk were polymerized following incubation with MTGase. In addition, MTGase-induced polymerization occurred earlier for β-casein and κ-casein isomers than for other milk proteins.

Key words: transglutaminase, milk protein, two-dimensional electrophoresis, proteomics

INTRODUCTION

Transglutaminase (TGase; EC 2.3.2.13) is an enzyme that catalyzes an acyl transfer reaction between the γ-carboxyamide of a protein-bound glutamine residue and a primary amine (Agyare and Damodaran, 2010). Transglutaminase is widely distributed in animal tissues, plants, and microorganisms. The extracellular microbial TGase (MTGase) from Streptovercillium mobaraense has become commercially available (Gerber et al., 1994). As MTGase can form intra- and intermolecular crosslinks, large-molecular-weight (MW) polymers with altered functionality are produced. Milk proteins have been shown to be substrates for crosslinking by MTGase and have attracted considerable attention in dairy research (Monogioudi et al., 2009). Caseins appear to be readily crosslinked by MTGase because of their flexible random-coil structures and the absence of disulfide bonds in αs1-CN and β-CN (O’Connell and Fox, 2000; Moon et al., 2009).

Microbial TGase can modify solubility, hydration, and heat stability of caseins, as well as their gelation, rheological, emulsifying, and renneting properties (Lorenzen et al., 2002). O’Sullivan et al. (2002) suggested that the treatment of milk with MTGase improves its heat stability, which is probably accomplished by preventing dissociation of κ-CN from micelles by crosslinking the caseins. Microbial TGase is a calcium-independent enzyme that can catalyze the formation of covalent ε-(γ-glutamyl)lysine crosslinks, which is important in improving the functional properties of milk proteins without loss of nutritional quality (Czernicka et al., 2009). However, some researchers reported the crosslinking of whey proteins such as β-LG when milk was treated with MTGase. The whey proteins tend to crosslink less efficiently than caseins because of their compact globular structures (Matsumura et al., 2000).

Recently, a proteomics approach has been used to study the milk proteins (Holland et al., 2011). Proteomics has emerged as a novel experimental approach to analyze several hundred proteins in complex mixtures using high-resolution 2-dimensional gel electrophoresis (2-DE) coupled with mass spectrometry (Gagnaire et al., 2009). In this method, proteins are separated according to their isoelectric point (pI) along a pH gradient by isoelectric focusing in the first dimension and according to their molecular weight by SDS-PAGE in the second dimension (Ong and Pandey, 2001). All protein spots that are resolved and detected can be qualitatively and quantitatively studied in relation to each other (Bahrman et al., 2004). Therefore, 2-DE combined with mass spectrometry has been used to separate and identify individual milk proteins of interest. However, the proteomics analysis of MTGase-induced polymerization of individual milk proteins during incubation has never been reported. In this study, we used SDS-PAGE and 2-DE coupled with MS to investigate
the effects of MTGase on the polymerization of milk proteins. The objective of this study was to analyze MTGase-induced polymerization of milk proteins using a proteomics approach.

**MATERIALS AND METHODS**

**Preparation of Milk Samples**

Fresh raw milk from a healthy Holstein-Friesian cow was obtained from a local farm in Taipei in northern Taiwan. The milk was skimmed at 5,000 × g for 20 min, and the skim milk (23.8 mg/mL) was collected and stored at 4°C. Microbial TGase from Streptoverticillium mobaraense (1 unit/mg) was obtained from Ajinomoto Co. Inc. (Activa TG-B, solution form; Ajinomoto Co. Inc., Tokyo, Japan). To investigate the effects of MTGase on the polymerization of milk proteins, milk samples with varying amounts of MTGase (0, 0.25, 0.5, 1.0, or 2.0 units/mL) were incubated at 30°C for 3 h. The resulting samples were heated to 80°C for 3 min to inactivate the MTGase. In this study, MTGase-induced polymerization of milk proteins during incubation was studied. The milk samples with (2.0 units/mL) or without MTGase were incubated at 30°C for 0, 1, 2, or 3 h.

**SDS-PAGE Analysis**

Milk samples with or without MTGase were analyzed by SDS-PAGE according to Hsieh and Chen (2008) and using a 12.5% separating gel and a 5% stacking gel. For each sample, 0.1 mL was mixed with 0.9 mL of buffer (2% SDS, 5% β-mercaptoethanol, 10% glycerol, 0.02% bromophenol blue, and 70 mM Tris-HCl, pH 6.8) and heated to 95°C for 5 min. The samples and a protein ladder were loaded into separate wells (6 μL/well). Following electrophoresis, the gels were stained with Coomassie Brilliant Blue R-250. The stained gels were digitized using an Epson perfection 1270 image scanner. The gels were scanned with a Typhoon 9200 imaging system (Amersham Pharmacia Biotech Inc., Piscataway, NJ) and analyzed using the PDQuest software package (version 7.3, Bio-Rad).

**2-DE PAGE**

Milk samples were analyzed by 2-DE. For the first separation, 100 μg of total milk protein was immobilized and loaded onto pH gradient (immobilized pH gradient, IPG) gel strips (pH 4–7, 18 cm; GE Healthcare, Burr Ridge, IL) that had been rehydrated for 12 h in a solution containing 7 M urea, 2 M thiourea, 4% 3-[3-cholamidopropyl]-dimethylammonio]-1-propanesulfonate, 40 mM Tris-base, 2% IPG ampholyte, 65 mM 1,4-dithioerythritol (DTE), and 0.0002% bromophenol blue. Isoelectric focusing of the IPG strips was performed using the IPGphor 3 IEF system (GE Healthcare) at 20°C and 6,000 V for a total of 60 kVh. The strips were equilibrated for 15 min in equilibration solution (50 mM Tris-HCl, pH 8.8, 6 M urea, 2% SDS, 30% glycerol, and 2% DTE) and added to the top of a vertical 12.5% SDS-PAGE gel with 0.5% agarose. The second electrophoresis step was performed using a Protean II xi Cell system (Bio-Rad) at 10 mA per gel for 1 h followed by 45 mA per gel for 5 h until the bromophenol blue reached the bottom of the gel. After electrophoresis, the gels were immersed in 10% methanol and 7% acetic acid for 30 min and were stained in 350 mL of Sypro Ruby protein gel stain solution (Molecular Probes Inc., Eugene, OR) overnight (Berggren et al., 2000). The developed gels were digitally scanned as 2-D images with a Typhoon 9200 imaging system (Amersham Pharmacia Biotech Inc., Piscataway, NJ) and analyzed using the PDQuest software package (version 7.3, Bio-Rad).

**Protein Digestion and MS Analysis**

Twenty-one selected milk protein spots were excised and destained by two 15-min washes in a solution that contained 250 μL of acetonitrile/50 mM ammonium bicarbonate (1:1 vol/vol). The gels were dried using a centrifugal vacuum concentrator. The cysteine residues in the samples were reduced and alkylated using DTE and iodoacetamide, respectively. For tryptic digestion, the gels were rehydrated in a tryptic solution (12.5 ng/mL) and incubated at 37°C for 16 h. Peptide fragments were extracted with an equal volume of 100% acetonitrile and 2% trifluoroacetic acid and sonicated in a water bath for 10 min. The extracted peptides were concentrated in a vacuum centrifuge. For matrix-assisted laser desorption/ionization-mass spectrometry (MALDI-MS) analysis, the extracted peptides were mixed 1:1 with a matrix solution (5 mg/mL of α-cyano-4-hydroxycinnamic acid in 50% acetonitrile, 0.1% vol/vol trifluoroacetic acid, and 2% wt/vol ammonium citrate) and spotted onto a 96-well format MALDI sample stage. Data were directly obtained using a quadrupole time-of-flight (Q-TOF) Ultima MALDI instrument (MALDI, Micromass, Manchester, UK).

**Protein Identification**

Peptide mass fingerprint data from MALDI-Q-TOF analyses were used to identify protein candidates in the
Swiss-Prot protein databases (http://www.expasy.ch/sprot) using the Mascot (http://www.matrixscience.com) search program (Gygi and Aebersold, 2000). Search parameters allowed for methionine oxidation, cysteine carbamidomethylation, one missed cleavage site, and a peptide mass tolerance of 0.25 Da (Morrissey and Downard, 2006). The product ion spectra generated by Q-TOF MS/MS were compared with those in the Swiss-Prot protein database, and an exact match was found using the Mascot search program (Ahram et al., 2002).

RESULTS AND DISCUSSION

Effects of MTGase on the Crosslinking of Milk Proteins

Microbial TGase is an acyltransferase that forms intra- and intermolecular crosslinks by isopeptide bond formation between peptide-bound glutamine and lysine residues (Garcia et al., 2007). Milk samples were incubated with various amounts of MTGase (0, 0.25, 0.5, 1.0, or 2.0 units/mL) for a 3-h period and analyzed by SDS-PAGE. The polymerization of β-CN, κ-CN, and a portion of αS-CN by MTGase into higher MW proteins was observed. The increase in high MW proteins of 200 kDa is shown in Figure 1, as evidenced by the increase in protein staining intensity at the top of the gels, which positively correlated with increasing amounts of MTGase. The components with higher MW

Figure 2. Changes in the SDS-PAGE profiles of milk proteins incubated with and without microbial transglutaminase (MTGase) at 30℃ for varying amounts of time. (A) Milk without MTGase; (B) milk with 2.0 units of MTGase/mL; M = protein marker.
likely resulted from casein (αS-CN, β-CN, and κ-CN) crosslinking. In addition, the staining intensity of β-CN and κ-CN decreased when 0.25 and 1.0 units/mL of MTGase were added, respectively, and the β-CN and κ-CN bands almost disappeared after the addition of 2.0 units/mL of MTGase. The disappearance of β-CN and κ-CN confirmed the presence of casein crosslinking because the ε-(γ-glutamyl) lysine isopeptide bonds formed in the crosslinked caseins by MTGase are difficult to dissociate using SDS and mercaptoethanol during SDS-PAGE analysis (Abd-Rabo et al., 2010). These results demonstrated that β-CN and κ-CN were crosslinked more readily by MTGase than was β-LG. However, β-LG could still be observed after the addition of 2.0 units/mL of MTGase. De Jong and Koppelman (2002) indicated that β-LG is a major globular whey protein, and globular proteins are poor substrates for MTGase because their active sites are rarely exposed (Tang and Ma, 2007).

Effects of Incubation Time on the Crosslinking of Milk Proteins by MTGase

Milk samples with or without MTGase (2.0 units/mL) were incubated at 30°C for 1, 2, or 3 h before analysis by SDS-PAGE (Figure 2). No significant changes were observed in the milk samples without MTGase treatment after a 3-h incubation period, indicating that protein polymerization did not occur in the absence of MTGase (Figure 2A). However, the amount of casein (αS-CN, β-CN, and κ-CN) in the MTGase-treated milk decreased with increasing incubation time (Figure 2B). As previously mentioned, the disappearance of caseins suggests the occurrence of polymerization because MTGase catalyzes an acyl transfer reaction between the γ-carboxyamide of a peptide- or protein-bound glutamine residue and a primary amine. de Kruif and Holt (2003) reported that the polymerization of β-CN and κ-CN induced by MTGase may be due to the specific location of the enzyme within the casein micelle, and the flexible conformation of caseins may promote catalysis by MTGase (Lee et al., 2002). Furthermore, SDS-PAGE demonstrated that the MTGase-induced crosslinking of β-CN and κ-CN was considerably faster than that of αS-CN. The susceptibility of αS-CN to catalysis by MTGase was lower than that of β-CN and κ-CN, which has been observed in several previous studies (Huppertz and de Kruif, 2007). The densitograms that correspond to SDS-PAGE analysis of the MTGase-containing milk samples are shown in Figure 3. The total intensity of the protein bands that correspond to αS-CN, β-CN, and κ-CN in the milk were 8,245.6, 6,677.2, and 586.6 arbitrary units (AU), respectively (Figure 3). Morris et al. (2000) reported that αS-CN, β-CN, and κ-CN are present in milk at a ratio of approximately 5:4:1. After the incubation of MTGase-containing milk for 3 h, the total intensity of αS-CN, β-CN, and κ-CN in the milk decreased from 8,245.6, 6,677.2, and 586.6 AU to 1,911.7, 0.0, and 66.2 AU, respectively.

Identification of Milk Proteins by 2-DE Analysis

O’Donnell et al. (2004) reported that 2-DE combined with MS could be used to identify milk proteins. The 2-DE image of milk proteins is shown in Figure 4. Twenty-one spots selected from the 2-DE gel were digested with trypsin, and the resulting peptides were analyzed by MS. These proteins were identified by comparison with mammalian protein sequences in the Swiss-Prot databases. In total, 21 proteins were assigned individual numbers and cataloged according to their MW and pI (Table 1). The identified proteins were grouped into isomers of BSA, αS1-CN, αS2-CN, β-CN, κ-CN, β-LG, and α-LA. The identified proteins were consistent with those identified by Chevalier et al. (2009). Spots 1 to 3 were isomers of BSA, spots 19 and 20 were isomers of β-LG, and spot 21 was α-LA; BSA, β-LG, and α-LA are major components of whey protein isolates (Elshereef et al., 2010). Moreover, spots 4 to 6, 7 to 9, 10 to 12, and 13 to 18 were isomers of αS1-CN, αS2-CN, β-CN, κ-CN, and β-LG on the 2-DE gel. Holland et al. (2004) reported that multiple protein forms on a 2-DE gel indicate the presence of co- and posttranslational modifications, which cause a shift in the MW. Phosphorylation or glycosylation can modify the molecular weight or pI of a protein (Barrabés et al., 2010). In addition, protein degradation may be responsible for multiple spots of the same protein. Chevalier et al. (2009) reported that caseins comprise 80% of milk proteins and are present in various forms that depend on varying glycosylation patterns and levels of degradation.

2-DE Analysis of the Effects of MTGase on Caseins and Whey Proteins

Milk samples with (2.0 units/mL) or without MTGase were incubated at 30°C for 1, 2, or 3 h before analysis by 2-DE gels (Figure 5). According to the 2-DE results, the β-CN isomers (spots 10–12) in the MTGase-treated milk were almost depleted after 1 h of incubation. However, a portion of the αS1-CN isomers (spots 4–6), αS2-CN isomers (spots 7–9), and κ-CN isomers (spots 13–18) disappeared after 2 h of incubation. We noticed that the profile of spot 4 was different from that of spot 6 (both αS1-CN). Spot 4 had a high fold change, which may have been dependent on a lower
concentration from the beginning. Furthermore, we also noticed that the profile of spot 13 was different from that of spot 16 (both κ-CN). Pisano et al. (1994) reported that κ-CN is a glycoprotein and that the O-glycosylation sites are in the C-terminal portion of the molecule. Similar to the results of Holland et al. (2005), spots 13 and 16 were identified as being triglycosylated and monoglycosylated κ-CN, respectively. According to our results, spot 16 had a higher fold change than spot 13, which suggests that monoglycosylated κ-CN is an excellent substrate for MTGase. During incubation, we observed that casein crosslinking rates were in the following order: β-CN > κ-CN > αS1-CN and αS2-CN. Bönisch et al. (2007) reported that the casein proteins possess a highly accessible and flexible open chain structure that makes them favorable substrates for MTGase. Furthermore, the amino acid sequence of β-CN contains 11 lysines and 20 glutamines, which makes it a better substrate for MTGase than αS1-CN and αS2-CN (Monogioudi et al., 2009). After incubation of milk with MTGase for 3 h, β-CN (spots 10–12) and κ-CN (spots 13–18) isomers were almost completely polymerized by MTGase, whereas the BSA (spots 1–3), αS1-CN (spots 4–6), αS2-CN (spots 7–9), β-LG (spots 19–20), and α-LA (spot 21) isomers were still clearly visible on the 2-DE gels. Lee et al. (2002) reported that whey proteins such as BSA, β-LG, and α-LA are globular proteins that are poor substrates for MTGase.

Densitograms corresponding to the 2-DE images of the MTGase-treated milk samples were generated and the fold changes of individual milk proteins are shown in Figure 6. The fold changes of β-CN and κ-CN isomers in the MTGase-treated milk decreased significantly with incubation time. The β-CN isomers in the MTGase-treated milk almost disappeared after 3 h of incubation (Figure 6A). The changes of spot 10 (β-CN), spot 11 (β-CN), and spot 12 (β-CN) in the MTGase-treated milk were 0.007-, 0.027-, and 0.023-
fold, respectively. This analysis revealed that 99.3% of spot 10 (β-CN), 97.3% of spot 11 (β-CN), and 97.7% of spot 12 (β-CN) were polymerized by MTGase after 3 h of incubation. Moreover, the κ-CN isomers in the MTGase-treated milk were almost depleted after 3 h of incubation (Figure 6B). The changes of spots 13 to 18 (κ-CN) in the MTGase-treated milk were 0.080-, 0.057-, 0.067-, 0.037-, 0.093-, and 0.040-fold, respectively. These results showed that the β-CN and κ-CN isomers were effective substrates for MTGase. However, only a portion of BSA (spots 1–3), αS1-CN (spots 4–6), αS2-CN (spots 7–9), β-LG (spots 19–20), and α-LA (spot 21) isomers were polymerized by MTGase after 3 h of incubation.

**Reaction Scheme for the Effect of MTGase on Milk Proteins**

Based on our results, a reaction scheme for the effect of MTGase on the polymerization of individual milk proteins is shown in Figure 7. The MTGase-mediated polymerization reaction includes 2 steps, the first being an enzymatic process in which MTGase catalyzes β-CN and κ-CN. Microbial TGase-induced polymerization occurs more readily for β-CN and κ-CN than for other milk proteins, which may be an effect of the specific location of MTGase within the casein micelle (de Kruif...
It is known that αS1-CN, αS2-CN, β-CN, and κ-CN are incorporated into casein micelles; however, some β-CN and κ-CN molecules are located in the outer region of casein micelles and are more readily catalyzed by MTGase (Smiddy et al., 2006). Furthermore, Sharma et al. (2001) reported that the porous nature of casein micelles allows MTGase to diffuse into the interior. Therefore, the flexible conformation of β-CN in casein micelles also allows for catalysis by MTGase. The second step involves MTGase-mediated catalysis of αS1-CN, αS2-CN, and whey proteins. In our study, a portion of BSA, αS1-CN, αS2-CN, β-LG, and α-LA were catalyzed by MTGase. However, the degree of polymerization of αS1-CN, αS2-CN, and whey proteins was less than that of β-CN and κ-CN. The aggregated milk proteins contained β-CN, κ-CN, and a portion of the BSA, αS1-CN, αS2-CN, β-LG, and α-LA fractions.

**CONCLUSIONS**

Proteomic analysis of the effects of MTGase on the polymerization of individual milk proteins was performed. Sodium dodecyl sulfate-PAGE and 2-DE analyses showed that MTGase catalyzed β-CN, κ-CN, and a portion of the BSA, αS1-CN, αS2-CN, β-LG, and α-LA fractions to form high MW polymers, and that the polymerization of β-CN and κ-CN occurred earlier than that of the other milk proteins. Moreover, β-CN and κ-CN are considered excellent substrates for MTGase. A proteomics-based approach is a useful and effective method to analyze individual milk proteins affected by MTGase.
