ABSTRACT

Luteolysis is a key event in cattle reproduction. A standard dose of exogenous PGF2α will induce full luteolysis in the majority of cows with a matured corpus luteum (CL). However, this will not occur in cows with a CL <5 d old. To date, it is not known whether a larger dose will have a more potent luteolytic effect in cows during early diestrus. The objective of this study was to characterize the effect of 2 doses of d-cloprostenol (150 and 300 μg) on the progesterone concentration, luteal diameter, and ovulation rate in nonlactating dairy cattle 96 to 132 h postovulation. Twenty nonlactating dairy cows were included in the study. Each cow received 2 treatments of d-cloprostenol in 2 consecutive cycles: a standard dose of 150 μg and a double dose of 300 μg. The cows were allocated randomly to 1 of 4 groups (5 cows in each group) according to the age of the CL at the time of treatment: 96, 108, 120, and 132 h. The exact time of ovulation was known within 12 h, because of twice per day ultrasound examination. The CL diameter and progesterone concentration were measured before treatment (d 0) and 2 and 4 d after treatment. Within each CL age group, the effect of d-cloprostenol dose on luteolysis was determined. More cows treated with double dose tended to have full luteolysis compared with the standard dose (8/10 vs. 4/10, respectively). This effect was only apparent in cows with CL of 120 and 132 h but not in earlier CL. The interval from treatment to ovulation was shorter (3.3 ± 0.1 d) in cows treated with a double dose than in cows treated with the standard dose (4.5 ± 0.4 d).

Key words: cow, progesterone, luteolysis, prostaglandin dose

INTRODUCTION

The corpus luteum (CL) of cattle is refractory to a single treatment of exogenous native PGF2α (25 mg of dinoprost, manufacturer’s recommended dose) within the first 4 d of the estrous cycle (estrus = d 0; Beal et al., 1980). Even 1 d later (d 5 of the estrous cycle), a similar dose of PGF2α failed to cause full luteolysis in treated heifers and cows (Rowson et al., 1972; Henricks et al., 1974). As a result, most PGF2α-based protocols of ovulation and estrous synchronization in cattle allow at least a period of 5.5 d between the previous ovulation and the administration of PGF2α (Ovsynch protocol; Pursley et al., 1995) so that the presence of a responsive CL is ensured in cows allocated to these types of protocols. However, a percentage of cows (depending on the study, 5 to 20%) fail to undergo full luteolysis following the PGF2α treatment of the Ovsynch protocol (Moreira et al., 2000; Gümen et al., 2003; Brusveen et al., 2009).

To study the effect of low progesterone on embryo development, Beltman and coworkers (2009) used a treatment protocol consisting of 3 treatments of luprostone (15 mg) 12 h apart, starting on d 3 postestrus in beef heifers (Beltman et al., 2009). By increasing the number of PGF2α treatments from single to multiple administrations, an earlier luteolytic response can be obtained. In the latter study (Beltman et al., 2009), most cows underwent partial luteolysis (67%) with decreased progesterone concentration, whereas only a few did not respond (22%) or develop full luteolysis (11%). Furthermore, an extra PGF2α administration 24 h after the initial PGF2α treatment of the Ovsynch protocol increased the percentage of cows with full luteolysis from 85 to 96% (Brusveen et al., 2009). This phenomenon is relevant to cattle reproduction, as cows with incomplete or partial luteolysis 2 d after PGF2α treatment have reduced chances of becoming pregnant after fixed time AI in an Ovsynch protocol (Souza et al., 2007). Unfortunately, this protocol increases the labor costs, resulting from additional handling of animals required to administer the second PGF2α treatment.

In addition to the age of the CL and the frequency of the luteolytic treatment, the dose of the luteolytic agent appears to be a factor that may influence the degree of luteolysis. Evidence shows that full luteolysis is achieved in more mares in early diestrus following a
single treatment of 500 μg of cloprostenol than after a standard dose of 250 μg (Cuervo-Arango and Newcombe, 2011). Similarly, the administration of 50 mg of dinoprostenol to dairy cows 3.5 d postovulation induced full luteolysis in 22% of treated cows (Cuervo-Arango et al., 2011). Cows with CL of 3.5 d old are thought to be refractory to a single standard treatment of PGF2α (Beal et al., 1980). However, to date no study has compared specifically the dose rate effect of a luteolytic agent on the degree of luteolysis in dairy cattle in early diestrus with different CL ages.

The objective of this study was to characterize the effect of 2 doses of d-cloprostenol (150 and 300 μg) on the progesterone concentration, luteal diameter and ovulation in nonlactating dairy cattle 84 to 132 h postovulation. The main hypothesis tested was that the larger dose would induce a greater decrease in progesterone concentration and luteal diameter 2 and 4 d after treatment.

MATERIALS AND METHODS

Animals

This trial was conducted from May to June 2011 at the Veterinary School Research Farm of the Universidad CEU Cardenal Herrera in Náquera, Spain (northern hemisphere). All animal procedures were handled in accordance with the Spanish Department of Agriculture Guide for Care and Use of Animals in Research, and they were approved by the Animal Welfare Committee of the Universidad CEU Cardenal Herrera.

A total of 20 nonlactating Holstein cows were used in the trial. The cows had been dry for at least 2 yr. The cows’ ages ranged from 4 to 10 yr [mean age of 6.7 ± 1.9 yr (±SEM)]. There were 5 nulliparous and 15 multiparous cows. At the beginning of the trial all animals were cyclic and had no apparent uterine or ovarian abnormalities confirmed by ultrasonography. The cows were fed alfalfa hay and cereal concentrate rations calculated for a maintenance diet for dry cows. The mean BCS was 3.5 ± 0.6 (range 2.5 to 4, scale 1 to 5) and the mean weight was 645 ± 47 kg (range 570 to 680 kg). All of the PGF (d-cloprostenol) injections were administered with single-dose syringes in semimembranosus or semitendinosus muscles with 18-gauge 3.5-cm needles.

Experimental Design

All cows were administered 25 mg of dinoprost (Enzaprost; CEVA Saúde Animal S.A. Barcelona, Spain) 14 d apart. The day beginning after the second dinoprost administration, the cows were scanned by rectal ultrasonography every 12 h for the detection of ovulation with an ultrasound scanner (SonoSite 180 Vet Plus; BCF Ultrasound Australasia, Nunawading, VIC, Australia) equipped with an 8-MHz linear-array transducer. Ovulation was detected as per the disappearance of the previously recorded preovulatory follicle and confirmed by the later development of a CL. Once a cow had ovulated, she was randomly allocated to 1 of the 4 CL age groups: (1) 84 to 96 h (n = 5), (2) 96 to 108 h (n = 5), (3) 108 to 120 h (n = 5), and (4) 120 to 132 h (n = 5). For simplicity, the CL age groups are referred to as the oldest possible age (96, 108, 120, and 132 h). The study followed a crossover design: for each CL age group, every cow received 2 treatments of d-cloprostenol (Dalmazin; Fatro Ibérica S.L., Barcelona, Spain) during 2 consecutive cycles. The treatments consisted of either a standard dose (recommended by the manufacturer) of 150 μg of d-cloprostenol (2 mL of Dalmazin) or a dose of 300 μg of d-cloprostenol (4 mL of Dalmazin; double the manufacturer’s recommended dose) i.m. For accurate detection of ovulation, after each treatment the cows were scanned every 12 h until ovulation was detected or until 7 d later, whatever happened first. If the cow had not ovulated within 7 d of treatment, she was administered 25 mg of dinoprost, and scanned for detection of ovulation every 12 h. After the consecutive ovulation of the second cycle, each cow received the remaining treatment dose of d-cloprostenol at the same interval postovulation as during the previous cycle and scanned daily for 7 d to determine CL size. Whether a cow received the standard or the double dose in the first or second cycle was chosen randomly.

For progesterone analysis, a blood sample was taken from the tail vein on each occasion (0, 2, and 4 d after treatment), in 5-mL heparinized tubes. The tubes were immediately centrifuged for 10 min at 2,000 × g. Aliquots of plasma were stored at −20°C for later assay determination. Concentrations of plasma progesterone were measured in a single assay, using enzyme immunoassay kits (Demeditec Diagnostics GmbH, Kiel-Wellsee, Germany) with a sensitivity of 0.04 ng/mL and an intraassay variation coefficient of 5%. A cow was classified as having full luteolysis when the progesterone concentration was below 1 ng/mL 4 d posttreatment.

The CL diameter was calculated by the average of 2 measurements taken at right angles with the electronic calipers when the frozen image of the CL was maximum.

Endpoints Analyzed

The endpoints analyzed were CL diameter and progesterone concentration just before (d 0), and 2 and 4 d after treatment. And whether the cow ovulated or not.
spontaneously (no treatment to induce ovulation was used in the study) within 7 d of treatment. If a cystic structure (follicle that never ruptured or collapsed but continued to grow until >2 cm in diameter) was present 7 d posttreatment, an extra blood sample was taken for progesterone determination and cyst classification: a cow with a luteal cyst had progesterone concentration >1 ng/mL, whereas <1 ng/mL with a follicular cyst.

### RESULTS

No cow ovulated in the 2 earliest CL age groups (96 and 108 h). However, 1 cow treated with a double dose of d-cloprostenol had full luteolysis, followed by the development of a luteal cyst (Table 1). In these 2 groups, the dose of d-cloprostenol had no effect on the progesterone concentration (Figure 1; \( P > 0.05 \)). However, the double dose of d-cloprostenol tended to induce a greater decrease in the posttreatment CL diameter in cows treated 108 h postovulation. In addition, in this group, a significant effect of dose by day interaction on the CL diameter was observed. This resulted from a slower increase 2 and 4 d posttreatment in the CL diameter of cows treated with the double dose (Figure 1).

In the 2 oldest CL groups (120 and 132 h), the double dose of d-cloprostenol tended to induce full luteolysis in more cows (8/10) than the standard dose (4/10; Table 1). Two cows with full luteolysis from the double dose groups did not ovulate but developed cystic ovaries (Table 1). Overall, 4 and 6 cows ovulated after treatment with the standard and double dose of d-cloprostenol, respectively (\( P > 0.05 \)). In these ovulating cows, the interval from treatment to ovulation was shorter (3.3 ± 0.1 d) than in cows administered the standard dose (4.5 ± 0.4 d).

For the CL age group of 120 h, the double dose of d-cloprostenol tended to induce a greater decrease in the posttreatment progesterone concentration and CL diameter (Figure 1; \( P < 0.05 \)). An effect (\( P < 0.05 \)) of dose by day interaction on the CL diameter was observed. For the oldest CL group (132 h), the double dose induced a greater decrease in the posttreatment progesterone concentration (\( P < 0.05 \)) and CL diameter (\( P < 0.1 \); Figure 1).

### Statistical Analyses

For each CL age group, a general linear model of variance with a repeated statement to account for autocorrelation between sequential observations of same individuals (Systat 13; Systat Software Inc., Chicago, IL) was performed. Two models were created, one for progesterone concentration and another for CL diameter. Each model had the same 2 fixed factors: dose of d-cloprostenol (2 levels: standard and double dose) and day relative to treatment (repeated observations: on d 0, 2, and 4 after treatment). If an effect of dose (standard vs. double) or an interaction of dose and day were or approached significance, data were examined further by Student’s \( t \)-test.

In cows with full luteolysis, the interval from treatment to ovulation of cows receiving the standard dose was compared with those treated with the double dose by unpaired Student’s \( t \)-test. Frequency data (number of cows with full luteolysis and percentage of ovulating cows) were analyzed by the Fisher exact test.

A probability of \( P < 0.05 \) indicated that a difference was significant and probabilities between \( P > 0.05 \) and \( P < 0.1 \) indicated that a difference approached significance. Data are presented as mean ± standard error of the mean, unless stated otherwise.
For cows treated with double doses of d-cloprostenol, the difference in progesterone concentration between 0 and 2 d posttreatment and with a CL of 120 and 132 h old (1.8 ± 0.59 and 1.7 ± 0.47 ng/mL, respectively) was greater \((P < 0.05)\) than that of cows with CL of 108 and 96 h old \((-0.39 ± 0.7\) and \(-0.31 ± 0.1\) ng/mL, respectively).

In cows with a CL of 132 h old, the progesterone concentration continued to decrease between 2 and 4 d after a treatment with the double dose, but not in cows...
EFFECTS OF D-CLOPROSTENOL DOSE AND CORPUS LUTEUM AGE IN NONLACTATING DAIRY COWS

The main hypothesis tested that a larger dose of d-cloprostenol would induce a greater decrease in progesterone concentration and luteal diameter 2 and 4 d after treatment cannot be accepted at all levels of CL age. The larger dose (300 μg) of d-cloprostenol was superior to the standard dose (150 μg) in terms of reducing progesterone concentration within 4 d of treatment, only in cows with a CL aged between 108 and 132 h (4.5 and 5.5 d) but not earlier. A 12-h gap in the CL age was sufficient to influence whether the dose of d-cloprostenol had an effect on the percentage of cows with full luteolysis. Therefore, the main strengths of this study were the crossover design with each cow acting as her own control for the main effects of dose and the timely calculation of the CL age (detection of ovulation every 12 h). This allowed having groups of cows with relatively homogenous CL ages (between 0 and 12 h difference). This, in part overcame the expected individual variation within groups resultant from their relatively small sample size.

It appears that the effect of dose on progesterone concentration becomes more apparent as the CL gets older: the double dose had no effect in cows with a CL aged between 96 and 108 h; this became a tendency in 120 h and finally had a significant effect when the CL was 132 h old. This finding may have clinical implications, as the cows enrolled in an Ovsynch protocol have a CL aged between 132 and 144 h at the time of the PGF2α treatment (Pursley et al., 1995). Along these lines, a large field study with lactating dairy cows involving Ovsynch-based synchronization programs with different doses of a luteolytic agent should be carried out. Then, it would be possible to elucidate whether increasing the dose of PGF2α is beneficial to achieve full luteolysis in a greater proportion of cows and so improve pregnancy rates (Souza et al., 2007; Martins et al., 2011).

The natural resistance of CL to exogenously induced luteolysis during early diestrus has been widely studied in ruminants (Tsai and Wiltbank, 1997; Tsai and Wiltbank, 1998; Skarzynski and Okuda, 1999; Mamluk et al., 1999; Levy et al., 2000; Sayre et al., 2000; Silva et al., 2000) and yet, it is not completely understood. Possible explanations are reduced availability of endothelin-1 (Levy et al., 2000) and increased availability of prostaglandin dehydrogenase (Silva et al., 2000) in early CL compared with mature CL. Endothelin-1 is a proteinaceous vasoconstrictor and steroidogenic cell modulator produced by endothelial cells in response to PGF2α that alters progesterone production in cattle (Girsh et al., 1996), whereas prostaglandin dehydrogenase metabolizes PGF2α to its inactive form, 15-keto-PGF2α in ewes (Silva et al., 2000). It is possible that providing a higher dose of exogenous PGF2α would override to some extent the antiluteolytic effect resultant from the increased availability of prostaglandin dehydrogenase and reduced concentration of ET-1 in the early CL.

The results of a similar study in mares (Cuervo-Arango and Newcombe, 2011) also showed a significant effect of d,l-cloprostenol dose on the percentage of mares with full luteolysis when it was administered at different stages of early diestrus. The difference became more apparent as the mares’ CL became older. In the latter study, 3 doses of d,l-cloprostenol were attempted: 250 (standard), 500, and 750 μg. The double dose induced a greater percentage of mares with full luteolysis

The CL groups refer to the age of the CL in hours at the time of treatment with a double (300 μg) or standard (150 μg) dose of d-CLO. P4: 0–2 d: difference in P4 concentration between just before and 2 d after treatment; P4: 2–4 d: difference in P4 concentration between 2 and 4 d after treatment. Within the 132-h CL group, the rate of P4 decrease between 2 and 4 d after treatment tended (P = 0.09) to be greater in cows treated with the double dose than in cows treated with the standard dose.
than did the standard dose but it was similar to that induced with 750 μg. This effect was only significant in mares with CL aged 96 to 104 h, but not earlier. Therefore, it seems that a threshold also exists upon which an increase in d-cloprostenol dosage does not result in an equivalent luteolytic effect.

A recent study (Stevenson and Phatak, 2010), showed a slight difference between dinoprost and d,l-cloprostenol in terms of inducing full luteolysis in lactating dairy cows (91.3 and 86.6%, respectively). Although, the luteolytic agents were administered as part of a standard Ovsynch protocol (CL ages between 132 and 144 h), it should be taken into account that the type of compound used might also influence the outcome of luteolysis in earlier stages of diestrus. Along those lines, 50 mg of dinoprost induced a 50% (2/4) incidence of full luteolysis in cows treated 108 h postovulation (Cuervo-Arango et al., 2011). This seems superior to the full luteolysis rate (20%) achieved with d-cloprostenol at the same interval postovulation in the current study.

The CL morphology seemed to be affected by the dose of d-cloprostenol to a greater extent and at an earlier stage than its functionality. The diameter of the CL and its ability to secrete progesterone do not always correlate well (Herzog et al., 2010). In a recent study (Cuervo-Arango et al., 2011), the CL diameter was reduced to a greater extent and for longer than the progesterone concentration, resultant from PGF2α-induced partial luteolysis compared with nontreated cows. The reason why the interval between treatment and ovulation in cows treated with double dose was shorter than that of cows treated with the standard dose is unknown. A possible explanation might be that the greater reduction in progesterone concentration, resultant from the larger dose, allowed a more rapid increase in LH with the subsequent advance in follicular maturation and ovulation. The negative effect that progesterone exerts on LH has been shown (Hannan et al., 2010).

CONCLUSIONS

Treatment with double dose of d-cloprostenol (300 μg) induced a greater proportion of full luteolysis in cows with a CL aged 120 to 132 h than the standard dose (150 μg). This effect was not apparent in cows with earlier CL. The CL diameter tended to be smaller in cows after treatment with double dose when they had a CL of 108 to 132 h old. A difference as little as 12 h in the CL age was sufficient to influence the effect of d-cloprostenol dose on the CL morphology and functionality. Cows treated with double dose of d-cloprostenol ovulated a day earlier than cows treated with the standard dose.
