ABSTRACT

Objectives were to evaluate the effects of a stable prepartum grouping strategy on innate immune parameters, antibody concentration, and cortisol and haptoglobin concentrations of Jersey cows. Cows (253 ± 3 d of gestation) were paired by gestation length and assigned randomly to the stable (all-in-all-out; AIAO) or traditional (TRD) treatment. In the AIAO treatment, groups of 44 cows were moved into a pen where they remained for 5 wk, whereas in the TRD treatment, approximately 10 cows were moved into a pen weekly to maintain stocking density (44 cows for 48 headlocks). Pens were identical in size and design and each pen received each treatment a total of 3 times (6 replicates; AIAO, n = 259; TRD, n = 308). A subgroup of cows (n = 34/treatment) was selected on wk 1 of each replicate from which blood was sampled weekly from d −14 to 14 (d 0 = calving) to determine polymorphonuclear leukocyte (PMNL) phagocytosis, oxidative burst, and expression of CD18 and L-selectin, hemogram, cortisol and glucose concentrations, and haptoglobin concentration. Another subgroup of cows (n = 40/treatment) selected on wk 1 of each replicate was treated with chicken egg ovalbumin on d −21, −7, and 7 and had blood sampled weekly from d −21 to 21 for determination of immunoglobulin G anti-ovalbumin. All cows (n = 149) had blood sampled weekly for nonesterified fatty acid (NEFA) and β-hydroxybutyrate (BHBA) concentrations from d −21 to 21. Treatment did not affect percentage of PMNL positive for phagocytosis and oxidative burst (AIAO = 64.3 ± 2.9% vs. TRD = 64.3 ± 2.9% geometric mean fluorescence intensity (GMFI)) and oxidative burst (AIAO = 7,667.99 ± 678.29 vs. TRD = 7,422.70 ± 682.91 GMFI). Similarly, treatment did not affect the percentage of PMNL expressing CD18 (AIAO = 96.3 ± 0.7% vs. TRD = 97.8 ± 0.7%) or L-selectin (AIAO = 44.1 ± 2.8% vs. TRD = 45.1 ± 2.8%) or the intensity of expression of CD18 (AIAO = 3,496.2 ± 396.5 vs. TRD = 3,598.5 ± 396.9 GMFI) and L-selectin (AIAO = 949.8 ± 22.0 vs. TRD = 940.4 ± 22.3 GMFI). Concentration of immunoglobulin G anti-ovalbumin was not affected by treatment (AIAO = 0.98 ± 0.05 vs. TRD = 0.98 ± 0.05 OD). The percentage of leukocytes classified as granulocyte (AIAO = 38.9 ± 1.5 vs. TRD 38.2 ± 1.5%) and the granulocyte:lymphocyte ratio (AIAO = 0.75 ± 0.04 vs. TRD = 0.75 ± 0.04) were not affected by treatment. Concentrations of cortisol (AIAO = 14.95 ± 1.73 vs. TRD = 18.07 ± 1.73 ng/mL), glucose (AIAO = 57.6 ± 1.5 vs. TRD = 60.0 ± 1.5 ng/mL), and haptoglobin (AIAO = 3.09 ± 0.48 vs. TRD = 3.51 ± 0.49 OD) were not affected by treatment. According to the current experiment, a stable prepartum grouping strategy does not improve innate immune parameters or antibody concentration compared with weekly prepartum regrouping.

Key words: dairy cow, regrouping, immune response

INTRODUCTION

Stressors elicit biological responses that are behavioral, neuroendocrine, autonomic, and immune in nature (Moberg, 2000). Several conditions (i.e., elevated temperature humidity index, excessive regrouping, high stocking density) to which prepartum cows are exposed are considered stressors and believed to have profound consequences to health and productive parameters because of their effects on immune, neuroendocrine, and behavioral responses. von Keyserlingk et al. (2008) demonstrated that within the first few hours and days after regrouping, lactating dairy cows that were moved to a new pen had reduced resting time, reduced feed
intake, and greater rate of displacement from the feed bunk. Accompanied by these behavioral changes, cows that were moved to a different pen had reduced milk yield on the day after regrouping (von Keyserlingk et al., 2008). Stress and pain associated with castration and dehorning cause neutrophilia, reduced secretion of tumor necrosis factor-α by PMNL, and reduced PMNL oxidative burst intensity (Ting et al., 2003; Doherty et al., 2007; Ballou et al., 2013), whereas stress associated with weaning and transport causes a reduction in circulating concentrations of immunoglobulin in pigs (Kojima et al., 2008). The peripartum period is the most delicate phase of a cow’s life because of important nutrient balance, hormonal, and immune changes associated with lactogenesis and parturition. Therefore, it has been suggested that prepartum cows subjected to regrouping could suffer more severe negative energy balance and immunosuppression as a consequence of either decreased feed intake or increased concentration of cortisol. Cook and Nordlund (2004) have suggested that, to eliminate stress related to reorganization of social order following regrouping, cows should be moved in groups to a prepartum pen and no new cows should enter these prepartum pens until all cows have calved. This is a similar concept to the all-in-all-out (AIAO) system that is commonly used in other food animal-producing systems (i.e., poultry and swine) to minimize the transmission of infectious diseases.

Reduced feed intake during the periparturient period is associated with increased concentrations of NEFA and BHBA, which have been associated with reduced myeloperoxidase activity of PMNL (Hammon et al., 2006). Furthermore, PMNL of cows diagnosed with metritis have reduced myeloperoxidase activity in the week of parturition (Hammon et al., 2006). On the other hand, exposure to stressors results in increased cortisol concentrations, which may affect concentrations of IgG and IgM (Mallard et al., 1997; Lacetera et al., 2005). Consequently, identifying management strategies that may affect DMI and concentrations of NEFA and BHBA and cause stress is important to reduce immunosuppression during the periparturient period.

The hypothesis of the current experiment were that a prepartum grouping strategy that reduces agonistic behavior (AIAO vs. weekly entry of new cows) would result in reduced cortisol concentration, improved PMNL activity (phagocytosis and oxidative burst), increased expression of adhesion molecules by PMNL (L-selectin and β2-integrins), increased IgG concentration in response to an ovalbumin challenge, and increased IgG concentration in colostrum. Therefore, the objectives of the current experiment were to evaluate if a stable prepartum grouping strategy (AIAO) would reduce concentrations of cortisol and improve innate immune parameters and antibody concentration during the peripartum compared with a traditional prepartum grouping strategy in which new cows are introduced weekly into the prepartum pen.

**MATERIALS AND METHODS**

Cows used in the current experiment are a subgroup of cows used in a larger experiment (Silva et al., 2013). Detailed description regarding facilities, management, and nutrition may be found in Silva et al. (2013). Briefly, the experiment was conducted from February 2011 to October 2012 in a dairy located in southern Minnesota. Throughout the experiment, Jersey cows were housed in cross-ventilated freestall barns. During the prepartum period (d −28 to 0; d 0 = calving), cows were housed in 1 of 2 freestall pens with 44 stalls and 48 headlocks that were identical in size and design. At the start of each replicate, the target stocking density was 100% of stalls and 91.6% of headlocks. From calving to d 21, all cows were housed in the same freestall pen with 240 stalls and 260 headlocks, and stocking density did not exceed 100 and 91.6% of stalls and headlocks, respectively. From d 21 until diagnosis of pregnancy 66 ± 3 d after AI, cows were housed in freestall barns with 240 stalls and 260 headlocks, and stocking density varied between 110 and 120% of headlocks and between 119% and 130% of stalls. Artificial lighting was provided during the prepartum (8 h of light and 16 h of dark) and postpartum (16 h of light and 8 h of dark) periods. All cows received the same TMR during the prepartum period, from calving to d 21, and after d 21. Diet compositions are described in Silva et al. (2013).

**Treatments**

Prepartum Jersey cows (≥ first lactation) were enrolled in the experiment at 253 ± 3 d of gestation. At enrollment, cows were balanced for parity (first or ≥ second lactation) and projected 305-d mature-equivalent milk yield and were sequentially assigned to 1 of the 2 study pens. Treatment applied to the study pens in the first replicate was determined randomly (coin toss). Cows assigned to the AIAO (n = 6 replicates with a total of 259 cows) grouping strategy were moved to the prepartum pen in groups of 44 cows (stocking density of 100% of stalls and 91.6% of headlocks), but no new cows were added to the AIAO pen until the end of the replicate. Cows assigned to the traditional (TRD, n = 6 replicates with a total of 308 cows) grouping strategy were moved to the prepartum pen as a group of 44 cows. Weekly thereafter, groups of 2 to 15 cows (median = 9 cows) were moved to the TRD pen to re-establish the desired stocking density (100% of stalls and 91.6% of...
BCS and Locomotion Scores

At enrollment and 1 ± 1, 28 ± 3, and 56 ± 3 d postpartum, all cows were scored for body condition (1 = emaciated and 5 = obese; 0.25-unit increments, as described by Ferguson et al., 1994) and locomotion (1 = normal locomotion and 5 = severely lame, as described by Sprecher et al., 1997).

Innate Immune Response Assays

In a subgroup of cows (AIAO = 34 and TRD = 34), ex vivo innate immune parameters were evaluated on d −14 ± 1, −7 ± 1, 0 ± 1, 7 ± 1, and 14 ± 1 as described by Hulbert et al. (2011). Samples were collected into heparinized evacuated tubes (Becton Dickinson Vacutainer Systems, Franklin Lakes, NJ). Expression of L-selectin and CD18 by peripheral PMNL was determined by indirect immunofluorescence staining. Briefly, the assay consisted of incubating 200 μL of whole blood at 4°C for 30 min with 5 μg/mL of anti-bovine CD62L (DU1-29, VMRD Inc., Pullman, WA) monoclonal antibody produced in mouse or 2.5 μg/mL of anti-bovine CD18 (BAQ30A, VMRD Inc.) monoclonal antibody produced in mouse. Erythrocytes were lysed with hypotonic PBS solution before being incubated with an anti-mouse IgG-fluorescein isothiocyanate (FITC) secondary polyclonal antibody (AbD Serotec, Raleigh, NC) diluted 1:400 in PBS solution (Sigma-Aldrich, St. Louis, MO). After washing the cells with PBS, samples were analyzed by flow cytometry. Blood samples from nondiseased cows were used as positive and negative controls in all assays. Negative controls consisted of incubating 200 μL of PBS solution instead of the monoclonal antibody. Phagocytic and oxidative burst activity of peripheral PMNL were determined upon challenge with enteropathogenic bacteria (Escherichia coli O118:H8) as described by Hulbert et al. (2011). Briefly, the assay to determine phagocytosis and oxidative burst consisted of incubating 200 μL of whole blood with 40 μL of 100 μM dihydrorhodamine 123 (Molecular Probes/Invitrogen, Eugene, OR), an oxidative-sensitive indicator, and 40 μL of fluorescently labeled bacteria (10⁹ cfu/mL) at 38.5°C for 15 min, with surface bacteria fluorescence removed using Trypan Blue solution (0.4%; Sigma-Aldrich). After washing with milliQ water (EMD Millipore, Billerica, MA) to remove excess dye, erythrocytes were lysed by the addition of hyper-concentrated PBS solution (Sigma-Aldrich). Finally, the cells were resuspended in PBS solution for immediate flow cytometry analyses. Blood from nondiseased cows was used as positive and negative controls. Unlabeled bacteria were used as negative controls for the phagocytosis assay and samples that received no dihydrorhodamine 123 served as negative controls for the oxidative burst assay. All flow cytometry data were collected on a BD FACS Canto II (BD Biosciences, Franklin Lakes, NJ) and analyzed using FlowJo 7.6.4 software (Tree Star Inc., San Carlos, CA). The PMNL population was identified on basis of forward- and side-scattered properties. After strictly gating the PMNL population, data from 3 parameters were collected for analysis: forward scatter, side scatter, and log fluorescence. Data are reported as PMNL intensity of phagocytosis, oxidative burst, and expression of CD18 and L-selectin molecules expressed in geometric mean fluorescence intensity (GMFI). Phagocytic and adhesion molecule intensity was an indirect indication of the number of phagocytosed bacteria and adhered molecules by PMNL, respectively. Oxidative burst intensity was an indirect indication of the amount of reactive oxygen species produced via oxidation of dihydrorhodamine 123. Furthermore, percentages of PMNL positive for phagocytosis, oxidative burst, and expression of CD18 and L-selectin molecules were calculated.

Hemogram

Blood sampled on d −14 ± 1, −7 ± 1, 0 ± 1, 7 ± 1, and 14 ± 1 were used for hemogram. Samples collected into evacuated tubes with EDTA (Becton Dickinson Vacutainer Systems) were analyzed using a Vet Scan HM2 (Abaxis, Union City, CA). Complete blood count was performed but only data referent to concentration of granulocytes relative to total leuko-
cytes and the granulocytes to lymphocytes ratio are reported.

**Antibody Concentration and Assay**

Cows received injections of 1 mg of chicken egg ovalbumin (Sigma-Aldrich) diluted in Quil A adjuvant (0.5 mg of Quil A/mL of PBS; Accurate Chemical & Scientific Corp., Westbury, NY) on d −21 ± 3, −7 ± 3, and 7 ± 3. Blood was sampled weekly from d −21 ± 3 to 21 ± 3 into evacuated tubes without anticoagulant (Becton Dickinson Vacutainer Systems) for determination of IgG anti-ovalbumin in serum by ELISA as described by Mallard et al. (1997). Only cows that received at least 2 doses of chicken egg ovalbumin, d −21 ± 3 and −7 ± 3, were retained for the analysis.

**Cortisol, Metabolites, and Haptoglobin Assays**

Blood samples collected into evacuated tubes without anticoagulant (Becton Dickinson Vacutainer Systems) on d −14 ± 1, −7 ± 1, 0 ± 1, 7 ± 1, and 14 ± 1 were used for determination of serum cortisol concentrations using a solid-phase RIA kit (Coat-a-Count, Siemens Medical Solutions Diagnostics, Los Angeles, CA). The intra- and interassay coefficients of variation (CV) were 5.8 and 11.7%, respectively.

Concentrations of NEFA were determined using a colorimetric assay (Wako Chemicals USA, Richmond, VA; Ballou et al., 2009) and concentrations of BHBA were determined enzymatically (Ranbut, Randox Laboratories, Antrim, UK; Ballou et al., 2009). Samples for determination of NEFA and BHBA were collected into evacuated tubes containing EDTA (Becton Dickinson Vacutainer Systems) on d −18 ± 3, −11 ± 3, −4 ± 3, 3 ± 3, 10 ± 3, 11 ± 3, and 18 ± 3. A plate reader (Spectramax 340; Molecular Devices, Sunnyvale, CA) was used to measure the absorbance for the colorimetric and enzymatic assays. Control serum (Randox Control Sera, Antrim, UK) was used for the NEFA and BHBA assays. The intraassay CV were 4.5 and 8.1% and the interassay CV were 8.2 and 10.1% for the NEFA and BHBA assays, respectively. Glucose concentration was determined by enzymatic reaction (Stanbio Laboratory, Boerne, TX). The intraassay CV were 5.3 and 9.1% for the glucose assay, respectively.

Haptoglobin concentration was determined by a colorimetric procedure as described by Hulbert et al. (2011) using a plate reader (Spectramax 340; Molecular Devices) to measure the absorbance. Samples were collected into evacuated tubes containing EDTA (Becton Dickinson Vacutainer Systems) on d −14 ± 1, −7 ± 1, 0 ± 1, 7 ± 1, and 14 ± 1. The intra- and interassay CV were 4.1 and 9.8%, respectively.

**Clinical Examination and Definitions of Diseases**

Cows were examined on d 1, 4 ± 1, 7 ± 1, 10 ± 1, and 13 ± 1 for the diagnosis of retained fetal membranes, metritis, and acute metritis. Retained fetal membranes was defined as retention of fetal membranes past 24 h postpartum. Metritis was defined as cows with watery, pink/brown, and fetid uterine discharge. Cows with symptoms of metritis and rectal temperature >39.5°C, or anorectic, or depressed were considered to have acute metritis (LeBlanc, 2010). All cows were observed once daily for displacement of abomasum and thrice daily for mastitis throughout their lactation. Data regarding incidence of displacement of abomasum and mastitis from study d 0 to 60 are reported herein.

On d 30 ± 3, the subgroup of 68 cows used to evaluate innate immune responses was examined for sub-clinical endometritis (≥10% of cells in the uterine cytology were PMNL; Kasimanickam et al., 2004) using the cytobrush technique (Cytobrush Plus, Cooper Surgical Inc., Trumbull, CT). After sample collection, the cytobrush was rolled onto a clean glass slide, which was stained with modified Wright-Giemsa stain (Protocol-Hema3, Biochemical Sciences, Swedesboro, NJ). Slides were evaluated twice at 400× magnification by one examiner who was blinded to the treatments. This same subgroup of cows was examined for clinical endometritis (exudate consisting of ≥50% of pus) using the Metricheck device (Simcro, Hamilton, New Zealand; McDougall et al., 2007) on study d 35 ± 3.

**Production Parameters**

Cows were milked thrice daily. Monthly, milk yield, milk fat and protein contents, and SCC were recorded for individual cows during the official DHIA test. Data regarding milk yield, milk fat and protein contents, and SCC were collected from study d 0 to 305. Energy-corrected milk was calculated for each cow using the formula (Orth, 1992)

\[
ECM (kg) = [(kg of milk) \times 0.327] + [(kg of fat) \times 12.95] + [(kg of protein) \times 7.2].
\]

All cows received recombinant bST (500 mg of Posilac; Elanco Animal Health, Greenfield, IN) every 10 d starting 57 ± 3 d postpartum.

**Statistical Analysis**

The experiment had a randomized design with pen as the experimental unit. In the first replicate, a coin was tossed to determine the treatment of each of the 2 study
In each of the replicates cows were balanced for parity (first or ≥ second lactation) and projected 305-d mature-equivalent milk yield and were assigned to 1 of the 2 study pens. The sample size was calculated based on the expected reduction in mean intensity of oxidative burst and reduction in mean intensity of phagocytosis on the day of calving. Thus, a sample size of 6 would be enough to demonstrate statistical difference when intensity of oxidative burst was reduced by 38% for cows in the TRD compared with cows in the AIAO treatment, when the standard deviation of intensity of oxidative burst on the day of calving is 2,000 GMFI (Mendonça et al., 2013).

Statistical analyses were conducted using SAS software (version 9.2; SAS/STAT, SAS Inst. Inc., Cary, NC). Binomial data were analyzed by logistic regression using the GLIMMIX procedure with the binary distribution and logit function. Continuous data were analyzed by ANOVA using the MIXED procedure. In all models, treatment (TRD vs. AIAO), replicate (1 to 6), and the interaction between treatment and replicate were included as a fixed effect. Pen was included as the random effect and treatment was nested within pen and replicate. For analysis of repeated measurements the repeated statement was used, the structure of covariance (auto-regressive, unstructured, or compound symmetry) was chosen according to the Bayesian Akaike information criteria, and time and the interaction between treatment and time were included in the model as fixed effects. Statistical significance was defined as $P \leq 0.05$ and statistical tendencies as $0.05 < P \leq 0.10$.

### RESULTS

Table 1. Percentage of cows calving male calves and twin births and incidence (%) of peripartum diseases of the subgroups of traditional (TRD) and all-in-all-out (AIAO) cows used to evaluate innate immune parameters and antibody concentration.

$^1$TRD = weekly entry of new cows into the prepartum pen; AIAO = no entry of new cows in the prepartum pen. Target stocking density was 100% of stalls and 91.6% of headlocks.

### Innate Immune Parameters and Antibody Concentration

Treatment ($P = 0.75$) and the interaction between treatment and day ($P = 0.68$) did not affect the percentage of leukocytes classified as granulocytes (Table 2). Similarly, the granulocytes:lymphocytes ratio was not affected by treatment ($P = 0.93$) or by the interaction between treatment and day ($P = 0.63$; Table 2). Treatment ($P = 0.98$) and the interaction between treatment and day ($P = 0.53$) did not affect the percentage of PMNL that were positive for phagocytosis and oxidative burst (Table 2). Among PMNL positive for phagocytosis and oxidative burst, treatment did not affect the intensity of phagocytosis ($P = 0.94$; Table 2) or the intensity of oxidative burst ($P = 0.99$; Table 2). The percentage of PMNL expressing CD18 was not affected by treatment (AIAO = 96.3 ± 0.7% vs. TRD = 97.8 ± 0.7%; $P = 0.17$) or by the interaction between treatment and day ($P = 0.54$). Similarly, intensity of ex-
pression of CD18 was not affected by treatment (AIAO = 3,496.2 ± 396.5 vs. TRD = 3,598.5 ± 396.9 GMFI; P = 0.60) or by the interaction between treatment and day (P = 0.21). The percentage of PMNL expressing L-selectin was not affected by treatment (AIAO = 44.1 ± 2.8 vs. TRD = 45.1 ± 2.8%; P = 0.81) or by the interaction between treatment and day (P = 0.56). Intensity of L-selectin expression was not affected by treatment (AIAO = 949.8 ± 22.0 vs. TRD = 940.4 ± 22.3 GMFI; P = 0.84) or by the interaction between treatment and day (P = 0.24; Table 2). The concentration of IgG in the colostrum did not (P = 0.93) differ between treatments (AIAO = 85.26 ± 5.42 vs. TRD = 93.38 ± 5.73 g/dL).

Cortisol Concentration, Metabolic Parameters, and Haptoglobin

Treatment did not (P = 0.48) affect serum cortisol concentration. On the other hand, we observed a tendency (P = 0.09) for the interaction between treatment and day to affect the serum cortisol concentration; on d -7, the cortisol concentration was higher for TRD than for AIAO cows (Figure 1). Concentration of glucose was not affected by treatment (P = 0.28) or by the interaction between treatment and day (P = 0.11; Figure 2). Similarly, treatment (P = 0.78) and the interaction between treatment and day (P = 0.72) did not affect the concentrations of NEFA (Table 2). Concentration of BHBA was not (P = 0.18) different between treatments and was not (P = 0.34) affected by the interaction between treatment and day (Table 2). Concentration of haptoglobin was not (P = 0.57) different between treatments, but the interaction between treatment and day tended (P = 0.10) to affect haptoglobin concentration because, on d 14 after calving, the haptoglobin concentration of TRD cows was higher than that of AIAO cows (Figure 3).

DISCUSSION

In the current experiment, the percentage of leukocytes classified as granulocytes and the ratio of granu-

³TRD (traditional prepartum grouping strategy) = weekly entry of new cows into the prepartum pen; AIAO (all-in-all-out prepartum grouping strategy) = no entry of new cows in the prepartum pen. Target stocking density was 100% of stalls and 91.6% of headlocks. Results are reported as LSM ± SE.

²Day = days relative to calving.

³Percentage of leukocytes classified as granulocytes.

⁴Geometric mean fluorescence intensity.
Neutrophilia has been related to stress and pain induced by castration and hot-iron dehorning (Ting et al., 2003; Doherty et al., 2007). Lobeck et al. (2012) reported that the rate of displacement from the feed bunk in the first 3 h after feeding was increased among TRD cows compared with AIAO cows. Furthermore, TRD cows had greater cortisol concentrations 7 d before calving than did AIAO cows. These findings suggest that TRD treatment resulted in more stress than the AIAO treatment and consequently in behavioral and neuroendocrine responses to stress. Nonetheless, behavioral changes in response to regrouping have been shown to be transient with behavior returning to pre-regrouping standards within a few hours or days after regrouping (von Keyserlingk et al., 2008; Lobeck et al., 2012). Therefore, it is not surprising that no alterations in hemogram parameters were observed as a consequence of treatment.

We observed no differences between AIAO and TRD cows regarding innate immune function (PMNL phagocytic and oxidative burst activities and expression of L-selectin and CD-18) or concentration of IgG anti-ovalbumin. The lack of effect of prepartum grouping strategy on innate immune function is surprising because TRD cows had slightly higher cortisol concentrations on d 7 before parturition than did AIAO cows, which was likely a consequence of greater stress (Nanda et al., 1990) among TRD cows, as observed by the greater rate of agonistic behavior at the feed bunk compared with AIAO cows (Lobeck et al., 2012). Cortisol modulates immune responses through different pathways. For example, cortisol downregulates expression of L-selectin and β2-integrins by neutrophils, adhesion molecules involved in the trafficking of neutrophils from the endothelium to the site of infection (Burton and Kehrli, 1995a; Burton et al., 1995b, 2005), which could compromise innate immune response. Furthermore, cortisol generally inhibits synthesis of proinflammatory cytokines (IL-4, IL-6, IL-12, IFN-γ) and favors the secretion of antiinflammatory and immunosuppressive (IL-10) cytokines (Wiegers et al., 2005). Thus, concentration of cortisol is also expected to affect production of antibodies through the blockade of cytokines secreted by CD4+ T helper 1 or CD4+ T helper 2 cells (Salak-Johnson and McGlone, 2007).

Continuous (24 h/d) and transient (4 h/d) exposure of male rats to adult fight-experienced male rats resulted in significant body mass loss on d 4 and 7 after onset of challenge (Stefanski et al., 2013). Interestingly, concentrations of monocytes and granulocytes were increased on d 3 and 7 after onset of challenge in rats continuously and transiently exposed to adult fight-experienced male rats, but only rats continuously exposed to adult fight-experienced male rats had reduced concentrations of CD4+ T helper and CD8 T cells (Stefanski et al., 2013). Thus, it appears that rats transiently exposed to adult fight-experienced male rats had sufficient time away from the stressor to partly alleviate the negative effects of stressful social confrontation on immune function (Stefanski et al., 2013). Transportation of calm and temperamental bulls resulted in a significant increase in cortisol concentration 24 h after transportation, but such an increase was more evident in temperamental bulls (Hulbert et al., 2011). Transportation resulted in...
In the current experiment, no differences in NEFA and BHBA concentrations or yield of ECM were observed between the AIAO and TRD treatments. Consequently, we speculate that energy status of AIAO and TRD cows was likely similar; thus, energy status should not have affected innate immune response and concentration of antibodies of cows in the AIAO and TRD treatments.

As explained previously, cows used in the current experiment represent a subgroup of cows used in a larger experiment (Silva et al., 2013). Among the cows used in the current experiment, we observed no differences in incidence of periparturient diseases between treatments. These findings are corroborated by the findings of Silva et al. (2013). Therefore, weekly regrouping of prepartum dairy cows does not appear to cause immunosuppression or to increase the incidence of periparturient diseases.

**CONCLUSIONS**

Weekly regrouping of prepartum dairy cows did not affect innate immune parameters or concentration of antibodies. This indicates that weekly entry of new cows into a prepartum pen is a minor stressor that, even though it produces a neuroendocrine response (i.e., a slight increase in cortisol concentration 7 d before calving), was insufficient to cause immunosuppression or to affect biological functions. It is important to observe that the only stressor in the current experiment that was eliminated by the AIAO strategy was the constant regrouping, whereas the number of headlocks and stalls and availability of feed and water were ideal. Furthermore, because of differences in temperament among breeds, it is not clear whether the AIAO strategy may have a different effect on breeds of dairy cattle other than Jersey.
