Influence of sodium chloride on the colloidal and rennet coagulation properties of concentrated casein micelle suspensions

Z. Zhao and M. Corredig
Department of Food Science, University of Guelph, Guelph, Ontario, N1G 2W1, Canada

ABSTRACT

The research investigated the influence of NaCl on the colloidal and rennet coagulation properties of concentrated milk. Milk was concentrated to 1×, 3×, and 5× using ultrafiltration. Rennet gelation was followed by rheology and diffusing wave spectroscopy. Soluble protein, total and diffusible calcium and phosphate, size, and zeta potential were also measured as a function of concentration history. In the presence of 300 mM NaCl, colloidal calcium phosphate solubilized and pH and the negative charge on the surface of casein micelles decreased. Increasing the volume fraction caused the formation of stiffer gels for both samples with or without NaCl. The addition of NaCl caused a significant increase in the bulk viscosity of the milk concentrated 5× and a decrease in turbidity. The concentration had no effect on the gelation time of control samples, nor on the kinetics of caseinomacropeptide release. On the other hand, rennet gelation was retarded by the addition of NaCl, and the gels showed lower elastic moduli compared with those obtained with control milk. Key words: casein micelles, sodium chloride, concentrated milk, rennet gelation

INTRODUCTION

Skim milk is a dispersion of proteins, minerals, and lactose. The major proteins in milk are caseins, which are present in the form of casein micelles. Casein micelles play an important role in the processing functionality of milk (Dalgleish, 2011; Dalgleish and Corredig, 2012). The structure of casein micelle has attracted the attention of scientists, and many models have been proposed to elucidate the structure of casein micelles over the past 50 yr (Holt, 1992, 1998; Horne, 2006; Dalgleish and Corredig, 2012). Colloidal calcium phosphate nanoclusters, with an average radius of 2.3 nm, are present in the inner core of the casein micelles and are surrounded by phosphorylated caseins (αS- and β-CN; Holt, 1998, 2004). κ-Casein molecules are located on the surface of the casein micelle, providing a polyelectrolyte brush of great importance to the colloidal stability of these protein particles (De Kruif and Zhulina, 1996).

The structure of casein micelles is affected by changes of environment, such as pH, temperature, and the presence of other minerals (Grufferty and Fox, 1985; Le Graët and Gaucheron, 1999; Carr et al., 2002; Huppertz and Fox, 2006). It has been reported that the addition of sodium chloride (NaCl) causes the solubilization of colloidal calcium phosphate, increases dissociation of caseins, and improves the solubility of milk concentrates (Mao et al., 2012); however, it may influence the processing functionality of casein micelles (Famelart et al., 1999; Gaucheron et al., 2000). Furthermore, the addition of NaCl decreases milk pH (Huppertz and Fox, 2006) and increases the hydration of casein micelle (Van Hooydonk et al., 1986).

Recent research demonstrated that when NaCl is added to 1× and 2× concentrated milk, there is dissolution of the colloidal calcium phosphate and release of caseins, with consequent changes of viscosity and turbidity (Zhao and Corredig, 2014). However, few studies conducted on the influence of NaCl on concentrated milk can be found, and further research is needed to better understand the effect of charge shielding and, in particular, the addition of NaCl on the processing properties of casein micelles.

Rennet coagulation is a critical processing step in cheesemaking. The rennet gelation involves 2 overlapping stages. The primary stage is the cleavage of κ-CN; once enough κ-CN (about 85–90%) is cleaved, the second stage, aggregation of the casein micelles, occurs with the formation of a gel network (Lucey, 2002; Liu et al., 2014). Concentration of skim milk using ultrafiltration increases the proteins and colloidal minerals in the retentate and decreases the average distance between casein micelles (Sandra et al., 2011). Previous researchers found that concentrated milk has a longer coagulation time and higher gel firming rate than non-concentrated milk (Dalgleish, 1980; Waungana et al.,...
However, recent research (Sandra et al., 2011) showed that concentration has no significant effect on the release of caseinomacropeptide (CMP) and coagulation time when the same amount of rennet is added to milk. Addition of NaCl was reported to increase the coagulation time of milk (Sbodio et al., 2006). It is still unknown how NaCl will influence the rennet coagulation of concentrated milk.

This research aims to better understand the influence of addition of NaCl before concentration on the structure of casein micelles and on the rennet gelation behavior of the concentrated milk. The concentration (1×, 3×, and 5×) was achieved by ultrafiltration based on the volume fraction. In our study, the rennet gelation process was followed by rheology and diffusing wave spectroscopy (DWS). Before rennet gelation, the changes in the physicochemical properties of concentrated milk were characterized by measuring total and soluble protein, total and diffusible calcium and phosphate, hydrodynamic size, zeta potential, and light scattering properties using DWS.

**MATERIALS AND METHODS**

**Preparation of Concentrated Milk**

Skim milk was obtained from a local dairy company (Crown Dairy, Guelph, ON, Canada). A total of 0.01% sodium azide was added immediately to prevent the bacterial growth. Sodium chloride (300 mmol/L) was added to milk and stirred for 15 min at room temperature. This concentration was chosen based on prior results, which showed a significant change in the size of the casein micelles and turbidity parameter of milk (Zhao and Corredig, 2014). All the samples were then equilibrated overnight in the refrigerator. After equilibration, aliquots of samples (1 L) were concentrated to different concentrations (1×, 3×, and 5×) using an ultrafiltration cartridge (10-kDa Millipore CDUF001LG, Fisher Scientific, Mississauga, ON, Canada) based on the volume reduction. All permeates were collected.

**Determination of Total and Soluble Protein Content**

The total protein was determined directly using a Dumas nitrogen analyzer (FP-528, Leco Inc., Lakeview Avenue, St. Joseph, MI). The protein concentration was calculated using 6.38 as conversion factor.

The soluble protein was defined as the fraction that did not sediment after ultracentrifugation at 100,000 × g for 1 h at 20°C (OptimaTM LE-80K ultracentrifuge with rotor type 70.1Ti, Beckman Coulter Canada Inc., Mississauga, Canada). The supernatants were then filtered through the 0.45-μm membrane (low protein binding, Fisher Scientific) before analysis.

**Determination of Total and Diffusible Calcium and Phosphate**

In this research, the 861 Advanced Compact IC (Ω Metrohm ion analysis, Metrohm Ltd., Herisau, Switzerland) was used to measure the total and diffusible calcium and phosphate in milk. The diffusible calcium and phosphate were defined as those present in the supernatant but not combined with the serum proteins. The sample preparation for both total and diffusible calcium and phosphate has been described in our previous research (Zhao and Corredig, 2014).

The calcium was determined using nonsuppressed ion chromatography (Rahimi-Yazdi et al., 2010). On the other hand, a CO2 suppressed ion chromatographic method was used to determine the total and diffusible phosphate. An anion exchange column (Metrosep A Supp5–150/4.0, Metrohm) packed with 5-μm polyvinyl alcohol with quaternary ammonium groups was employed. Sodium hydrogen carbonate and sodium carbonate solutions were used to prepare the mobile phase (1.0 mM sodium carbonate and 4 mM sodium hydroxide). Samples were eluted at a flow rate of 0.5 mL/min.

**Addition of Rennet and k-CN Hydrolysis**

Before the addition of rennet, milk samples were equilibrated at 30°C for at least 20 min. The rennet used was Chymax Ultra (Chr. Hansen, Milwaukee, WI) with average strength of 790 (±5%) international milk clotting units (IMCU)/mL. The rennet was diluted 100-fold in MilliQ water (Thermo Fisher Scientific, Burlington, Canada) before addition to milk. The diluted rennet was added to milk with a proportion of 4 μL/mL of milk. The final concentration of rennet in milk was 0.031 IMCU/mL. Milk samples were collected for 30 s after rennet addition before further analysis. The gelation process was carried out at 30°C.

The release of CMP by rennet was monitored using an established method (Lopez-Fandino et al., 1993). Rennet at the concentration defined above was added to the milk sample, which was then immediately divided into 2-mL aliquots in different test tubes. Samples were incubated at 30°C, and the reaction was stopped at designated times (every 10 min) by addition of 4 mL of 3% trichloroacetic acid. After overnight storage in refrigerator, the supernatant was collected and then centrifuged at 4,500 × g for 15 min at 22°C (Eppendorf centrifuge, 5415D, Mississauga, Canada). The obtained superna-
tants were then filtered through using 0.45-μm filters (syringe driven filters, Fisher Scientific). The content of CMP was then determined using reverse phase-HPLC. The HPLC was an Ultimate3000 LC (Thermo Scientific, Burlington, ON, Canada) with degasser, pump, auto-sampler, and UV detector (set to 210 nm). The sample (100 μL) was injected on a column (Pharmacia Biotech μRPC C2/C18 ST 4.6/100, Piscataway, NJ), with a Vydac C-4 guard column, Mandel Scientific Co. Inc., Guelph, ON, Canada), and elution was carried out with 0.1% trifluoroacetic acid (TFA) in water and 0.1% TFA in 90% acetonitrile in a nonlinear gradient (Lopez-Fandino et al., 1993) at 40°C. The total peak area of the chromatograms was integrated using Chromeleon 7.2 Data System Software (Thermo Scientific). The maximum peak area at plateau was considered as 100% of the CMP released.

**Light Scattering**

Zeta potential and the average apparent radius of the casein micelles were determined by Dynamic light scattering (Zetasizer Nano, Malvern Instruments, Worcestershire, UK). All samples were diluted 1,000 times with corresponding filtered (0.2-μm nylon filters, Fisher Scientific) UF permeates and analyzed.

Transmission DWS was also used to investigate the colloidal properties and to monitor the rennet gelation process of casein micelles in situ, as previously reported (Alexander et al., 2006). The output result from DWS is a time-dependent correlation function, as expressed by the following equation:

\[
g(t) \approx \frac{\left(\frac{L}{\tau^8} + \frac{4}{3}\right)\left(\frac{6t}{\tau}\right)^{1/2}}{\left\{1 + \frac{8t}{3\tau}\right\} \sinh \left[\frac{L}{\tau^8} \left(\frac{6t}{\tau}\right)^{1/2}\right] + \frac{4}{3} \frac{6t}{\tau} \cosh \left[\frac{L}{\tau^8} \left(\frac{6t}{\tau}\right)^{1/2}\right]\}^{1/2}\],
\]

where \( g \) is an autocorrelation function, \( t \) is time, \( L \) is the sample thickness and \( \tau \) characteristic decay time, \( \tau = 1/\alpha^2 D \), \( \alpha \) is the wave vector \( (\alpha = 2\pi n/\lambda) \), where \( n \) is the refractive index of the continuous phase and \( \lambda \) is the wavelength; Weitz et al., 1993), \( D \) is the diffusion coefficient, and \( \tau^8 \) is the transport mean free path, which represents the length scale over which the direction of the light passing through a sample has been fully randomized (Alexander et al., 2006). The value of \( \tau^8 \) can be calculated from the total intensity of the scattered light from the sample, and the laser intensity was previously calibrated using standard latex spheres of diameter 260 nm (Portland Duke Scientific, Palo Alto, CA). However, this relation only holds true in freely diffusive systems. Once the particle dynamics are changed to a subdiffusive motion, the quantity \( t/\tau \) in [1] must be substituted by \( k_0 = (\Delta r^2(t))/\Delta t \), where \( k \) is the mean square distance, \( r \) is distance, and \( t \) is the time over which one wants to average. In this case, the mean square displacement can be used to determine changes in the particles’ degrees of freedom, which is defined as the mobility of a scattering particle around its average position (Sandra et al., 2007; Cucheval et al., 2009).

Before the measurement, all samples undiluted were transferred into an optical glass cuvette (Hellma Canada Ltd., Concord, Ontario, Canada) with a 5-mm path length and then placed in a water bath maintained at 25°C. A solid-state laser light with a wavelength of 532 nm and a power of 350 mW (Coherent, Santa Clara, CA) was used to illuminate the samples. Scattered light intensity was collected in transmission mode and analyzed using software designed specifically for the equipment (Mediavention Inc., ON, Canada). Correlation functions and intensity of transmitted scattered light were measured at intervals of 2 min. The viscosity and refractive index of the continuous phase used to calculate the radius were 1.021 × 10⁻³ Pa·s and 1.34, respectively (Gaygadzhiev et al., 2008). For renneting measurements, correlation functions and intensity of transmitted scattered light were measured for 2 min (118-s collection, 2-s break) until gelation. The gelation process was performed at 30°C. The aggregation point was defined graphically, as the time of rapid increase of the radius.

**Rheology**

The rheometer was used to measure the apparent viscosity of samples and follow the gel formation process. The apparent viscosity of different samples before renneting was measured using a shear rate ramp from 10 to 100 s⁻¹ applied with a controlled stress rheometer (AR 1000, TA Instruments Ltd., New Castle, DE) at 25°C. The sample was loaded on a cone and plate geometry with a set gap of 0.51 mm. The values are reported for viscosity measured at 100 s⁻¹.

The gel formation process of skim and concentrated milk was followed by oscillatory measurements, using a constant strain of 0.01 and a frequency of 1 Hz. In this case, a concentric cylinder (28 and 30 mm inner and outer cylinders diameter, respectively) and an external water bath (Isotemp 3016, Fisher Scientific) were used to control the temperature at 30°C. Aliquots (20 mL) of sample were transferred to the cylinder within 5 min after the addition of chymosin. The milk gelation point was defined as the point when the elastic modulus (\( G' \)) and viscous modulus (\( G'' \)) cross over (\( \tan \delta = 1 \)); Lucey
et al., 1998). This point corresponds to a steep increase in the storage modulus \((G')\) over time.

**Statistical Analysis**

Experiments were carried out at least in triplicate. Analysis of variance and Tukey honestly significant difference were carried out on the experimental measurements with 95% confidence level using Minitab statistical package release 15 (Minitab Inc., State College, PA).

**RESULTS AND DISCUSSION**

**Composition of Soluble Fraction and Zeta Potential of Casein Micelles**

Three different levels of concentration were tested, with and without addition of 300 mM NaCl, corresponding to 1×, 3×, and 5× of the original skim milk, and a total protein of 3.2, 9, and 13% (wt/vol) (Table 1). The amount of soluble protein was statistically different in samples of 1× milk containing 300 mM NaCl \((P < 0.05)\) compared with control. On the other hand, no differences were detected for the 3× and 5× concentrated samples, compared with control. In all cases, about 30% of the total protein was recovered in the centrifugal supernatants.

As previously reported in the literature (Grufferty and Fox, 1985; Gaucheron et al., 2000; Huppertz and Fox, 2006), the addition of NaCl in milk significantly \((P < 0.05\%\) reduced the pH of both unconcentrated and concentrated milk, from 6.66 to 6.54 for milk containing 300 mM NaCl (Table 1). It is also important to note that the pH values of milk were not significantly different from 1× milk after concentration, in contrast with what was reported in the literature (Waungana et al., 1999; Karlsson et al., 2007). The difference is due to the fact that, in previous work, ultrafiltration was combined with diafiltration, causing further changes in mineral equilibrium.

Table 1 also summarizes the values of zeta potential of casein micelles, measured after redilution in their corresponding serum. In control milk the zeta potential was around −21 mV, and concentration had no significant effect (Table 1). The addition of 300 mM NaCl significantly \((P < 0.05)\) decreased the zeta potential of casein micelles, compared with control without NaCl, and in the concentrated samples, it was significantly \((P < 0.05)\) lower after redilution. The decrease with NaCl was induced by the screening effect of NaCl, reduced the electrophoretic mobility of the casein micelles, by a decrease in the electrostatic charge and thickness of the electrical double layer (Bouchoux et al., 2009; Bouchoux et al., 2010). However, it further decreased with concentration history, possibly because of a difference in the overall soluble ions present in the serum phase because of membrane filtration.

All samples (with or without NaCl) showed no significant differences in hydrodynamic radius after redilution (86 ± 2 nm), indicating no aggregation of the casein micelles, in agreement with previous reports (Huppertz and Fox, 2006). Figure 1 describes the changes in total and diffusible calcium and phosphate at the 3 concentrations for milk with and without NaCl. The total calcium and phosphate increased with concentration, and the addition of NaCl caused a decrease in the amount of calcium and phosphate recovered in the suspensions for 3× and 5× milk. After the addition of NaCl, the diffusible calcium and phosphate increased significantly compared with milk without NaCl (Figure 1C, 1D). These results clearly indicated that the addition of NaCl caused the solubilization of calcium and phosphate from the casein micelles. These changes would further explain the decrease in electrophoretic mobility of the casein micelles in concentrated suspensions with NaCl (Table 1). The results are in full agreement with previous reports (Le Graët and Gaucheron, 1999; Huppertz and Fox, 2006; Sbodio et al., 2006). Addition of NaCl decreased the colloidal calcium present in the micellar suspensions (calculated as the difference between total and diffusible); the value of colloidal calcium decreased

from 309 ± 26 mg/kg per gram of casein for 1× milk to
270 ± 30 mg/kg per gram of casein after the addition
of 300 mM NaCl. The lower level of colloidal calcium
was consistent in the NaCl suspensions, independently
on concentration.

**Apparent Viscosity**

Figure 2 shows the changes in the apparent viscosity,
measured at a shear rate of 100 s⁻¹, for milk samples
concentrated with or without NaCl. The viscosity of
milk increased with concentration. With the addition of
NaCl, the viscosity of the concentrates significantly (P
< 0.05) increased, whereas the 1× milk did not change.
In 5× concentrated milk the values changed from 8.7 ±
0.1 to 12.1 ± 0.3 mPa·s.

It has been previously reported that the addition
of NaCl causes a reduction of the mean free distance
between casein micelles (Karlsson et al., 2007), and the
closer proximity of the micelles is the reason for the in-

crease in the milk viscosity. It has been recently shown that the addition of NaCl also increases the concentration of soluble casein, contributing to an increase in the bulk viscosity of the casein suspensions (Famelart et al., 1999; Zhao and Corredig, 2014). Other authors reported a similar effect of NaCl in sodium caseinate solutions, and the increase in viscosity was attributed to an increase in osmotic pressure as well as an increase in the protein voluminosity (Abd El-Salam et al., 1987). The presence of NaCl decreases the overall charge of the proteins by shielding those charges, causing an increase in protein-protein interactions.

**Turbidity**

The turbidity parameter ($1/l^*$) was measured by transmission DWS, without dilution (Figure 3). As expected turbidity increased in 1× to 3× concentrated milk, because of the increased scattering events in a given space (Sandra et al., 2011). The closer spacing between casein micelles will cause the light scattering to be randomized faster, resulting in the decrease of the $l^*$. The additional increase in concentration from 3× to 5× did not further increase the turbidity, and no significant difference could be detected between these 2 concentrations. According to previous research, the turbidity of milk fit well to the theoretically predicted values for a hard-sphere system up to a concentration factor 3.2 (Dahbi et al., 2010). A maximum turbidity value was obtained at a concentration factor 3.9, and further increase of concentration factor led to decrease of turbidity, because of the occurrence of interparticle interactions at high concentration (Krishnakutti Nair et al., 2014). The addition of 300 mM NaCl to milk caused a significant ($P < 0.05$) decrease of the turbidity parameter at all concentrations. The turbidity parameter is a function of the optical properties of the scattering particles as well as a structure factor. At the low concentration (<4× for milk), the system can be regarded as free diffusing (Krishnakutti Nair et al., 2014). The negative charge on the surface of casein micelles decreased only slightly with NaCl addition, suggesting that sufficient charge repulsion still existed between these protein particles. The interparticle interactions, therefore, could be considered negligible, $S(q) = 1$. Therefore, the turbidity parameter is only influenced by the scattering form factor $F(q)$, where $q$ is the scattering vector, which is related to the size of casein micelles and refractive index contrast between the scatterers and serum. From the results of dynamic light scattering, all samples, after redilution, showed no significant change in the radius of casein micelles with addition of NaCl. The decrease in the turbidity parameter with NaCl in concentrated suspensions can be attributed to the differences in the refractive index between the protein particles and the serum, and it is due to the changes of serum refractive index as a result of dissolution of colloidal calcium phosphate and casein release (Zhao and Corredig, 2014).

**Rennet-Induced Gelation**

The effect of NaCl on the kinetics of CMP release is shown in Figure 4. As previously shown for milk concentrated by ultrafiltration (Sandra et al., 2011), CMP release did not differ with concentration in control milk (no NaCl; data not shown). The presence of 300 mM NaCl caused a decrease in the rate of the CMP release, in agreement with previous literature (Gatti and Pires, 1994; Famelart et al., 1999). However, the kinetics for suspensions containing NaCl were not significantly different ($P < 0.05$), regardless of concentration factor. All 3 samples reached about 85% CMP cleavage at about 80 min, compared with those of control milk, which required only 60 min to reach the same critical point for aggregation.

Figure 5 shows the changes of the DWS parameters (radius and $1/l^*$) as a function of time, after addition of rennet. The apparent radii were corrected by the Beenakker-Mazur formalism (Beenakker and Mazur, 1984). The $1/l^*$ increased with increasing concentration (Figure 3), and for better comparison of the gelation behavior, it was normalized (Figure 5). The $1/l^*$ parameter was initially constant, showing an increase.
with time before the gelation point, indicated by a steep increase in the radius. The behavior of $1/l^*$ was fully consistent with previous literature observations (Sandra et al., 2011). It has been previously shown that the turbidity parameter shows a sharp increase in untreated milk at about 70% CMP release. At this stage, the casein micelles are still free diffusing, but their spatial organization is changing because of a decrease in steric repulsion between the particles and a change in the refractive index contrast. Figure 5 shows that samples with and without NaCl had a similar behavior, with a leveling off of the $1/l^*$ for $1\times$ milk at the point of gelation, as shown in the literature (Sandra et al., 2011). At the higher concentrations, the turbidity parameter did not level off, both for NaCl and control samples. This may suggest that rearrangements occur to the structure of the gel. Whereas at $5\times$ concentration behavior of the $1/l^*$ with the addition of NaCl did not differ, a delay in the onset was shown for casein suspensions containing NaCl at $1\times$ and $3\times$ concentrations. This was partly caused by the delay in the CMP release (Figure 4). The gelation point, as measured both by DWS or rheology (Figure 5 and Table 2), was indeed retarded in casein suspensions containing NaCl compared with the corresponding control, at all concentrations. In control samples, aggregation occurred around 60 min, consistent with the data reported for CMP release (Table 2). The aggregation point did not change with concentration. The addition of NaCl caused a delayed increase of radius (Figure 5). Unlike the case of control milk with no NaCl, the onset of aggregation differed for these samples, whereby the rapid increase of radius happened after 100 min for $1\times$ milk, and the time shifted to 80 and 65 min for $3\times$ and $5\times$ milk, respectively. The differences in the aggregation behavior as a function of time with concentration could not be attributed to the primary stage of renneting, as the CMP release was not significantly different between samples containing NaCl at different concentration. These results would suggest that when concentrated, casein micelles destabilization will occur at a lower CMP release in the presence of

charge shielding (300 mM NaCl). These results were in full agreement with previous reports (Sharma et al., 1994; Le Feunteun et al., 2012).

The development of elastic ($G'$) modulus and the loss tangent ($\tan \delta$) during the rennet gelation process is summarized in Figure 6. Both samples with or without NaCl showed the formation of a stiff network but with different gelation times. Table 2 also summarizes the stiffness of the gels after 45 min from the gelation point. The curd-firming rate increased with concentration, in full agreement with previous results (Sharma and Hill, 1993; Guinee et al., 1996). It is well understood that gels formed from UF-concentrated milk are stiffer compared with gels made from control unconcentrated milk, simply because of the higher numbers of bonds forming between the proteins. In addition, the increased volume fraction of casein micelles due to UF concentration reduces the average distance between micelles, which increased the frequency of collisions and the contact area in the gel network, contributing to the increased curd-firming rate (Waungana et al., 1997; Mishra et al., 2005). The differences in firming rate are in line with previous results. It has been reported that addition of NaCl not only can affect the cleavage rate of $\kappa$-CN but can also influence the aggregation of renneted casein micelles; at NaCl concentrations higher than 200 mM, the rate of aggregation significantly decreases (Bansal et al., 2008).

In the presence of NaCl, consistent with the DWS observations, the time of gelation increased, and a significant ($P < 0.05$) difference with concentration existed. All samples showed lower stiffness than the same samples without NaCl. The loss tangent values for samples without NaCl addition reached a plateau around 0.27 regardless of concentration, as previously reported (Sandra et al., 2011). Similar loss tangent plateau values (0.26) were reached for samples containing 300 mM NaCl. Higher $\tan \delta$ value indicates higher rearrangement and flexibility of the structure and more susceptibility to syneresis (Mishra et al., 2005). All the gels formed in this research had similar $\tan \delta$ values, except those with 300 mM NaCl, which showed a lower $\tan \delta$ value.

$^a$$^b$Values within different superscript letters are significantly different ($P < 0.05$).

$^c$Values are means of 3 separate experiments, with error indicating standard deviation. The $G'$ was measured after 45 min from the gelation point, defined as $\delta < 45^\circ$. Aggregation time was measured by diffusing wave spectroscopy as onset of radius increase.
indicating both the NaCl addition and concentration have no effect on the final milk gel types. It is important to note that at the high concentrations, in both control and NaCl suspensions, the turbidity parameter did not reach a plateau. The negative effect of NaCl on the coagulation of milk has been ascribed to the screening of the positively charged cluster of κ-CN and of the chymosin, which inhibit the interaction between chymosin and κ-CN and decrease the enzymatic rate (Visser et al., 1987). However, the addition of NaCl influenced both the primary and secondary stage of rennet coagulation. This effect could only partly be attributed to a decrease in the rate of κ-CN hydrolysis. In the presence of NaCl, gelation time differed depending on concentration, and at the higher concentrations, gelation occurred before 80% of the CMP was released. This was not the case for control milk. The change is not related only to the decreased average distance between casein micelles, but to the decreased charge and increased solvation after NaCl addition (Famelart et al., 1999) and, most importantly, to the release of colloidal calcium and dissociation of the casein micelles. Hence, it can be concluded that although the rheological properties of the gels were similar, protein rearrangements still occurred in these gels.

CONCLUSIONS

Addition of NaCl led to a significant increase in the rennet coagulation time. It is important to note that during the UF process, the sodium chloride present in the serum phase was also partly removed. The final concentration of NaCl was 280 and 260 mmol/L for 3× and 5× milk, respectively. The presence of high concentration NaCl inhibited gelation and showed a decrease in the gel stiffness compared with the corresponding control. The results of this work put into question the current understanding of the effect of concentration on rennet-induced aggregation of casein micelles and the role that soluble and colloidal calcium phosphate play in the secondary stage of aggregation. A better understanding of the aggregation in concentrated milk can be beneficial to the application of modified casein micelles as an ingredient in food products.
