**ABSTRACT**

*Lactococcus lactis* is a gram-positive bacterium used extensively in the dairy industry and food fermentation, and its biological characteristics are usually improved through genetic manipulation. However, poor transformation efficiency was the main restriction factor for the construction of engineered strains. In this study, the transformation efficiency of *L. lactis* F44 showed a 56.1-fold increase in acid condition (pH 5.0); meanwhile, erythromycin stress (0.04 µg/mL) promoted the transformation efficiency more significantly (76.9-fold). Notably, the transformation efficiency of F44e (*L. lactis* F44 harboring empty pLEB124) increased up to 149.1-fold under the synergistic stresses of acid and erythromycin. In addition, the gene expression of some DNA binding proteins (DprA, RadA, RadC, RecA, RecQ, and SsbA) changed correspondingly. Especially for radA, 25.1-fold improvement was detected when F44e was exposed to pH 5.0. Overexpression of some DNA binding proteins could improve the transformation efficiency. The results suggested that acid or erythromycin stress could improve the transformation efficiency of *L. lactis* through regulating gene expression of DNA binding proteins. We have proposed a simple but promising strategy for improving the transformation efficiency of *L. lactis* and other hard-transformed microorganisms.

**Key words:** *Lactococcus lactis*, transformation efficiency, acid/erythromycin stress, DNA binding protein

---

**INTRODUCTION**

*Lactococcus lactis* has been widely used in food fermentation, such as cheese, yogurt, pickle, and so on (Song et al., 2017). Moreover, it plays an important role in food preservation due to the secretion of lactic acid and nisin. Nisin, a bacteriocin consisting of 34 AA, was approved by the Joint Food and Agriculture Organization/World Health Organization as a safe food additive in 1969 and had been licensed in many countries. Recently, nisin had also been proved to have potential for the treatment of tissue infection and cancer (Shin et al., 2016). To improve nisin yield, genetic manipulation has been applied in the construction of engineered strains and proved to be an effective method (Zhang et al., 2016; Ni et al., 2017). However, it is difficult for exogenous DNA to be delivered into *L. lactis*. Improvement of transformation efficiency (TE) is urgently needed for genetic manipulation of *L. lactis*.

Electrotransformation has been widely used for genetic transformation in bacteria since its invention in the 1980s (Neumann et al., 1982; Xie and Tsong, 1993). Bacterial TE could be affected by several parameters, such as competent cell concentration, plasmid size, electroporation time, field strength, and so on (Lu et al., 2014; Papagianni and Papamichael, 2014). Wu et al. (2009) improved TE by adjusting the field strength. Papagianni et al. (2007) achieved the goal by manipulating cell density.

Interestingly, dozens of bacteria could absorb and recombine exogenous DNA into their own genome spontaneously (Fontaine et al., 2015). The recombination process works with the assistance of several DNA binding proteins (DBP), such as DprA, RadA, and RecQ (Claverys and Martin, 2003). Lots of single-strand DNA binding proteins could maintain the stability of genome, and some of them are tightly associated with stress tolerance (Calhoun and Kwon, 2011; Zhu et al., 2015; Riber et al., 2016). On the other hand, TE was improved when the cells were exposed to adverse fac-
tors, and the expression of stress-associated genes could be upregulated correspondingly (Holo and Nes, 1989; Slager et al., 2014).

To enhance the efficiency of genetic manipulation, we tried to improve TE of *L. lactis* F44. The significant improvement of TE was observed under acid or erythromycin stress, or both. To explore the mechanism, we detected the expression levels of 6 representative DBP genes (*dprA*, *radA*, *radC*, *recA*, *recQ*, and *ssbA*) by quantitative real-time (qRT) PCR; the transcriptional levels of genes of interest were improved discriminately under acid or erythromycin stress, or both. Overexpression assays indicated that TE was closely related to the upregulation of the DBP. This work shed light on the improvement of TE for the hardly transformed strains and provided a promising strategy for a wider application of *L. lactis*.

**MATERIALS AND METHODS**

**Bacterial Strains, Plasmids, and Media**

*Escherichia coli* TG1 was grown at 37°C with shaking at 220 rpm in Luria-Bertani broth, which was used for cloning of plasmids pLEB124 and pNZ8048. *Lactococcus lactis* F44 was used as the original strain for the following experiments (Zhang et al., 2014). *Lactococcus lactis* F44e was constructed harboring the empty vector pLEB124, which contains constitutive p45 promoter and erythromycin resistance. All of the *L. lactis* strains were grown in seed medium (wt/vol; peptone 1.5%, yeast extract 1.5%, sucrose 1.5%, KH2PO4 2.0%, NaCl 0.15%, and MgSO4·7H2O 0.015%) at 30°C without agitation. The pH value was adjusted to 7.2 by 10 M NaOH before autoclaving at 115°C for 30 min. Erythromycin (5 µg/mL) was added to the medium for F44e. Chloramphenicol (5 µg/mL) was added in seed medium after the electroporation of empty vector pNZ8048.

**Cell Growth Assay**

*Lactococcus lactis* F44 and F44e were incubated for 3 generations and cultured in seed medium with a different pH value (7.0, 6.0, and 5.0). Optical density was measured at 600 nm every 2 h with a TU-1810 spectrophotometer (Persee, Beijing, China) to monitor cell growth. Similarly, growth of *L. lactis* F44 was also measured in the seed medium with different erythromycin concentrations (0, 0.01, 0.02, 0.03, and 0.04 µg/mL). In addition, the growth of *L. lactis* F44 and F44e were observed on acid solid medium. Bacterial cultures were diluted to 10^{-7} by 0.9% NaCl solution and then spread 100 µL on seed medium plates with different pH values (7.0, 6.0, and 5.0; without antibiotic). Colony-forming units were measured every 12 h.

**Electrotransformation**

*Lactococcus lactis* F44 and F44e were used as the targets for the electrotransformation. The strains were cultivated in the seed medium for 3 generations, then diluted 100-fold in secondary medium (seed medium supplemented with 1.5% sucrose and 1.5% glycine). The pH of secondary medium was adjusted to 7.0, 6.0, or 5.0 by 10% HCl (wt/vol) or 10 M NaOH before being used. Ampicillin was added to the medium at the final concentration of 20 µg/mL when the strains were cultured at 30°C for 6 h. After incubation at 30°C for 1 h, cells were harvested by centrifugation at 5,000 rpm for 5 min at 4°C. The cells were centrifuged and washed 3 times, then resuspended with ice-cold washing buffer (containing 6.846% sucrose, 10% glycerine). Finally, the cell density was adjusted to 10^9 cfu/mL.

For electrotransformation, 1 µg (about 6 µL) of pNZ8048 was added and gently mixed with 50 µL of competent cells. The mixture was transferred into an ice-cold electroporation cuvette (2 mm gap). After a single electrical pulse at 2.4 kV/cm, the cuvette was washed immediately with 1 mL of seed medium and incubated at 30°C for 3 h, then spread on the seed medium supplemented with chloramphenicol at the final concentration of 5 µg/mL. The number of mutants was counted after incubation at 30°C for 2 d (Wu et al., 2009; Zhou et al., 2015; Joan et al., 2016). All of the experiments were conducted in triplicate and the average value was recorded, similarly hereinafter.

**RNA Isolation and Transcriptional Analysis by qRT-PCR**

*Lactococcus lactis* F44 and F44e were cultivated overnight in the seed medium and treated at different pH (7.0, 6.0, 5.0, and 4.0) respectively for 1 h. Otherwise, *L. lactis* F44 was cultivated in the medium with different erythromycin concentrations (0, 0.01, 0.02, 0.03, and 0.04 µg/mL) for 1 h. Fifty-milliliter cultures ΔZR RNAMiniPrep kit (ZYMO Research, Orange County, CA) according to the manufacturer’s instructions. The synthesis of cDNA was carried out with the TIANscript RT Kit (Fermentas, New York, NY) according to the manufacturer’s protocol. The qRT-PCR were carried out in white 96-well LightCycler® 480 Multiwell Plates on the LightCycler® 480 (Roche Diagnostics, Penzberg, Germany) with Power SYBR Green PCR Master Mix (Applied Biosystems) according to the manufacturer’s instructions. The primers are listed in Supplemental Table S1 (https://doi.org/10.3168/jds.2017-13101).
Reactions were run in triplicate on 3 independent experiments for each condition. The qRT-PCR conditions were as follows: 1 cycle at 95°C for 10 min, 40 cycles of denaturation at 95°C for 10s, annealing at 55°C for 10s, and extension at 72°C for 20 s. The 16S rRNA gene was used as an internal control to normalize cycle threshold (C_T) values. The relative quantification of expression was calculated using the 2^−ΔΔCT method after the threshold cycle (Cheon et al., 2012; Li et al., 2015; Zhang et al., 2016).

**Construction of Overexpression Strains**

Genomic DNA of *L. lactis* F44 (mid-exponential phase of growth) was extracted with TIANamp Bacterial DNA kit (Tiangen Biotech, Beijing, China) following the manufacturer’s protocol. However, a preliminary cell disruption was carried out with 200 mg/mL of lysozyme solution. The genes of interest were amplified from genomic DNA of *L. lactis* F44 with the corresponding primers as listed in Supplemental Table S2 ([https://doi.org/10.3168/jds.2017-13101](https://doi.org/10.3168/jds.2017-13101)). The PCR products and pLEB124 were digested by BamHI and Smal and were recovered from agarose gels. All DNA fragments were ligated into the shuttle vector pLEB124 and then transferred into the competent *E. coli* TG1. Subsequently, *E. coli* TG1 were plated onto Luria-Bertani broth agar with 50 µg/mL of erythromycin and analyzed with colony PCR. After the extraction from *E. coli* TG1, all the plasmids were introduced into competent *L. lactis* F44 by electroporation using the MicroPulser Electroporator (Bio-Rad, Hercules, CA). In addition, the competence of engineering strains was prepared at pH 5.0 and then applied to the TE assay.

**RESULTS**

**Growth Characteristics of *L. lactis* F44 and F44e Under Different Acid or Erythromycin Stress, or Both**

We tested the growth character of *L. lactis* F44 and F44e at different pH (7.0, 6.0, and 5.0). The biomass decreased along with the declining of initial pH value of medium (Figure 1A), and the final pH values were approximating to 4.6 (Supplemental Figure S1; [https://doi.org/10.3168/jds.2017-13101](https://doi.org/10.3168/jds.2017-13101)). Apparently, acid stress had significant inhibitory effects on the growth of these strains. Likewise, erythromycin could also inhibit the growth of *L. lactis*. Therefore, we investigated the growth of *L. lactis* F44 under different erythromycin concentrations from 0 to 5 µg/mL and concluded that the sublethal concentrations of erythromycin ranged from 0.01 to 0.05 µg/mL. As shown in Figure 1B, the...
final biomass and growth rate of *L. lactis* F44 decreased with the increase of erythromycin concentration.

To further explore the influence of acid stress or erythromycin on *L. lactis*, the colony-forming units were detected by using *L. lactis* F44 and F44e (Figure 1C). The results showed that acid stress could inhibit the growth of *L. lactis*. An obvious colony on medium plates with pH 5.0 could only be found after 36 h of cultivation, and the colony size was smaller (data not shown). Few colonies of F44e were observed in pH 6.0 and 7.0 than that of F44. Interestingly, more colonies of *L. lactis* F44e were observed in acid conditions (pH 5.0) compared with *L. lactis* F44 (Figure 1C). Therefore, we speculated that the increased survival rate of *L. lactis* F44e comparing with F44 under acid stress might result from the activation of some intrinsic factor by erythromycin.

**TE of *L. lactis* Influenced by Acid or Erythromycin**

Previous studies showed that several bacterial TE were improved under the stress of antibiotics or concentrated NaCl (Palomino et al., 2010; Shanker and Federle, 2017). Therefore, it was speculated that acid or erythromycin, or both, could improve the TE of *L. lactis* F44. As shown in Figure 2A and Supplemental Figure S2 (https://doi.org/10.3168/jds.2017-13101), the TE of *L. lactis* F44 and F44e at pH 5.0 could increase up to 56.1- and 149.1-fold compared with that at pH 7.0, respectively. Moreover, the TE of *L. lactis* F44e with 5 µg/mL of erythromycin at pH 5.0 was 350-fold higher than that of *L. lactis* F44 without erythromycin stimulation at pH 7.0. The results indicated that TE of *L. lactis* F44 could be improved under acid and erythromycin stresses. Furthermore, we examined the erythromycin effect on TE of *L. lactis* F44. As shown in Figure 2B and Supplemental Figure S3 (https://doi.org/10.3168/jds.2017-13101), more positive colonies were obtained under acute erythromycin stress. Especially, the TE of *L. lactis* F44 (with 0.04 µg/mL of erythromycin) could be increased up to 76.9-fold compared with the control (no erythromycin added). These results further verified that erythromycin could improve TE of *L. lactis* F44 without the influence of pLEB124.

**Transcriptional Levels of DBP Genes Under Acid or Erythromycin Stress**

To assess the transcriptional levels of DBP under acid or erythromycin stress, or both, the transcripts of *dprA*, *radA*, *radC*, *recA*, *recQ*, *ssbA* in *L. lactis* F44 and F44e were monitored by qRT-PCR. The results showed that the expression level of these DBP genes increased along with the pH value decreasing in *L. lactis* F44 (Figure 3A and Supplemental Table S3, https://doi.org/10.3168/jds.2017-13101). Likewise, the same trend was observed in *L. lactis* F44e, and the expression levels of these genes increased more obviously, especially for *dprA*, *radA*, and *ssbA* (Figure 3B and Supplemental Table S4, https://doi.org/10.3168/jds.2017-13101), suggesting that erythromycin stress could also induce the expression increase of the DBP genes. As shown in Figure 3C and Supplemental Table S5 (https://doi.org/10.3168/jds.2017-13101), the expression levels of these genes increased with the intensification of erythromycin stress. These results verified that the response to environmental stress might be a trigger to the expression of DBP, resulting in the increased TE of *L. lactis*. 

![Figure 2](https://doi.org/10.3168/jds.2017-13101) Transformation efficiency (TE) of *Lactococcus lactis* influenced by acid and erythromycin. The TE was indicated by colony-forming units per microgram of pNZ8048. (A) The TE of *L. lactis* F44 and F44e under acid stress; competence cells were prepared after culturing in secondary mediums with different pH. (B) The TE of *L. lactis* F44 influenced by erythromycin. Competence cells were prepared at different erythromycin concentrations (0, 0.01, 0.02, 0.03, and 0.04 µg/mL). Error bars are SD from 3 independent experiments. *P* < 0.05, **P** < 0.01; *t*-test.
Effects of DBP Overexpression on TE of L. lactis F44

To investigate the influence of DBP on TE, we overexpressed these genes in L. lactis F44 and measured the TE of the engineering strains, respectively. As shown in Figure 4, the increased expression levels of DBP genes, especially dprA (2.9-fold) and ssbA (3.0-fold), has a strong effect on TE of L. lactis F44.

DISCUSSION

In the present work, we reported for the first time that acid or erythromycin stress could significantly \((P < 0.05)\) improve the TE of L. lactis. Moreover, the qRT-PCR results showed that the expression level of DBP genes was remarkably enhanced correspondingly. We also explored the effect of 6 DBP on TE through the overexpression assays.

Lactococcus lactis, a safe microorganism for humans and animals, has been widely used in the dairy industry (Rodrigues et al., 2016). Meanwhile, bio-engineered strains were usually used for the production of the industrially valuable compound (Zhang et al., 2014). However, the construction of engineered strains was hindered by low TE, similar to some gram-positive bacteria. In this study, we first found that TE of L. lactis was significantly \((P < 0.05)\) improved under acid stress (Figure 2A and Supplemental Figure S2, https://doi.org/10.3168/jds.2017-13101). In addition, the TE improvement of L. lactis F44 was more significant \((P < 0.05)\) than that of F44 (Figure 2A and Supplemental Figure S2, https://doi.org/10.3168/jds.2017-13101).
which indicated that erythromycin stress could also promote TE of _L. lactis_. To further verify this speculation, we tested TE of _L. lactis_ F44 under erythromycin stress with various concentrations (Figure 2B and Supplemental Figure S3, https://doi.org/10.3168/jds.2017-13101). The results showed that erythromycin could significantly (_P_ < 0.01) improve TE of _L. lactis_ also.

Some DBP are closely related to genomic stability; their expression levels would be improved when the cell was exposed to adverse factors (Burghout et al., 2007; Liang et al., 2013). Acid or erythromycin could result in the growth inhibition and TE improvement of _L. lactis_ F44, which inspired us to investigate the related mechanism. The expression levels of several DBP genes were enhanced significantly under acid stress (Figure 3A). It was speculated that the instability of DNA under acid stress could trigger the higher expression of some DBP genes (Karas et al., 2015). Moreover, a similar result was obtained under erythromycin stress (Figure 3C). Thus, we inferred that the transformation efficiency was associated with the higher expression levels of DBP genes under acid or erythromycin stress.

The DprA and SsbA could bind with the exogenous single-strand DNA to maintain its stability (Quevillon-Cheruel et al., 2012). Moreover, DNA repair proteins RadA and RadC play important roles in response to DNA damaging agents, methyl methanesulfonate, hydroxyurea, and UV radiation (Burghout et al., 2007; Liang et al., 2013). In addition, RecA is responsible for searching the corresponding homologous region on genome, and RecQ (helicase) could repetitively unwind and reanneal double-stranded DNA regions during the homologous recombination (Harami et al., 2017; Kochugaeva et al., 2017). Six representative DBP were overexpressed for further verification, and the results demonstrated that DBP played important roles in TE.

On the basis of our results, the TE of _L. lactis_ F44 could be improved under acid or erythromycin stress. Moreover, we confirmed that the interaction between TE and DBP was involved in acid/erythromycin stress response, which might shed light on the potential application of _L. lactis_ in the food and dairy industries.

**CONCLUSIONS**

In this study, we first reported that the TE of _L. lactis_ F44 could be improved significantly (_P_ < 0.05) by acid or erythromycin stress, or both. Further analysis showed that higher TE of F44 under acid or erythromycin stress, or both, was mediated with the increased expression of DBP. _Lactococcus lactis_ may be engineered more easily and used more widely in dairy industry based on our discoveries. Remarkably, this work also provided a novel method for genetic manipulation of hardly transformed bacteria.
