INTRODUCTION

Goat milk distinguishes itself from cow milk by higher digestibility, distinct alkalinity, higher buffering capacity, and presence of certain medicinal and therapeutic values (de Almeida Júnior et al., 2015); therefore, the production and fabrication of goat cheese has shown a growing trend in recent years. Cheese, a dairy product, has been part of the human diet for centuries and greatly affects human nutrition. Artisanal cheeses are manufactured in farmhouses following traditional techniques without the deliberate addition of selected starter cultures. They are typically characterized by a unique taste due to the spontaneous fermentation of unpasteurized milk and are greatly appreciated by consumers around the world. Reports show that their organoleptic characteristics correlate strongly with nutritional characteristics and the environmental contamination level of milk used for cheese production, the manufacturing process, and the presence of appropriate lactic acid bacteria (*LAB*) for fermentation (Carafa et al., 2015). In general, cheese production comprises 2 different microbiological steps, in which different *LAB* are involved. The first step, namely the manufacturing of cheese, requires starter LAB; the second step, ripening of the cheese, takes advantages of secondary microbiota nonstarter LAB (*NSLAB*; Di Grigoli et al., 2015), which are typically used in raw milk cheeses (Carafa et al., 2015). Fermentation properties of the *NSLAB* strongly affect the sensorial characteristics of the finished cheese.

The family of *NSLAB* consists of mostly facultative heterofermentative mesophilic lactobacilli species such as *Lactobacillus casei*, *Lactobacillus paracasei*, *Lactobacillus rhamnosus*, and *Lactobacillus plantarum*. It also contains of other genera such as *Pediococcus*, *Leuconostoc*, and *Micrococcus* (Franciosi et al., 2009; Piras et al., 2013; Bozoudi et al., 2016). Typically *NSLAB* grow after cheese brining, as they are resistant to heat and acid treatment that occur during cheese manufacturing and maturation. Bacterial autolysis pro-
vokes the release of enzymes during the final months of a long maturation process (Martínez et al., 2011; Lazzi et al., 2016). Although industrial cheese production is now well established, the NSLAB composition remains an uncontrolled factor and is suspected to be the cause of inconsistent quality of hard and semihard cheeses (Briggiler-Marcó et al., 2007; Burns et al., 2012). In fact, reports show that alterations in the dominant strains of NSLAB can lead to the formation of off-flavors and biogenic amines in addition to the possibility of gas blowing (Di Cagno et al., 2012). Therefore, to ensure consistency in cheese manufacturing and improve its sensory properties, potent NSLAB strains should be carefully selected when used as adjuncts for controlling the adventitious growth of undesirable NSLAB.

Mediterranean countries are producers of goat milk that is mostly used for cheese production (Juan et al., 2016). Indeed, traditional dairy products derived from goat milk represent a viable sector in the national economy of many Mediterranean countries, such as Spain, Greece, and Turkey, among others (Navarro-Alarcón et al., 2011; Pacheco Da Silva et al., 2016). In most Mediterranean countries, cheeses of raw goat milk represent a significant proportion of ripened cheeses (Serhan et al., 2010).

The most promising bacteria for adjunct cultures are those isolated from indigenous microflora of traditional products. In the present study, we isolated and characterized LAB from artisanal semihard goat cheeses of different Mediterranean countries for developing specific NSLAB. We then evaluated salt tolerance, acidification, autolytic activity, and enzymatic activity of the NSLAB.

MATERIALS AND METHODS

Cheese Samples

Eight semihard raw goat milk cheeses were purchased from local stores of 4 Mediterranean areas, namely, Ibores (sample A), Tenerife (sample B), and Babia (sample C) from Spain, Batzos (sample D) and Xinotyri (sample E) from Greece, Sepet (sample F) and Tulumn (sample G) from Turkey, and Darfiyeh (sample H) from Lebanon.

Microbiological Analysis

To obtain abundant NSLAB from these cheeses, 2 portions (about 10 g) per sample were collected using a sterile knife, specifically from the rind (sampled from the first 5 mm on each side of the cheese, including the edges) and the core (sampled from the center of cheese). The samples were then mixed for continuous microbiological analysis. Cheese samples were homogenized following the procedure described by Tsafarakidou et al. (2016). Briefly, cheese samples were homogenized with 90 mL of sterile 20 g/L sodium citrate solution at 45°C in a Stomacher 400 laboratory blender (Seward, London, UK) for 4 min at maximum speed. Dilutions (1/10) of the homogenates were prepared with a sterile solution of 0.85% (wt/vol) sodium chloride and then plated on de Man, Rogosa, and Sharpe (MRS; pH 5.7) agar plates that were incubated under anaerobic conditions at 30°C for 5 d before presumptive lactobacilli examination. Fifteen colonies per sample were randomly picked from the MRS agar plates, totaling to 120 colonies. Twenty-five colonies, which were gram-positive, catalase-negative, and able to grow at 15 and 45°C, were selected for the next test. Finally, pure cultures were frozen (−80°C) in MRS broth containing 20% (vol/vol) glycerol for storage. Isolates were activated by successive transfer in their respective medium and incubation at 37°C for production.

Identification of Isolates

Isolates were identified using the 16S rDNA sequencing method. Briefly, genomic DNA was extracted using the E.Z.N.A. bacterial DNA kit (Omega Bio-Tek, Norcross, GA) and amplified by the 16S rDNA universal pair of primers 27F: 5′-AGAGTTTGATCCTGGCTCAG-3′, and 1492R: 5′-TACGGTTACCTTGTTACGACTT-3′. The amplified products were sequenced by Sangon Biotech Co. Ltd. (Shanghai, China). Sequence similarity searches were performed by comparing the isolated sequences with the ones collected in the GenBank using the BLAST search program of the National Centre for Biotechnology Information (http://www.ncbi.nlm.nih.gov).

Technological Characterization

Salt Tolerance. The ability of the strains to grow in increasing saline solutions of 2, 6, and 10% (wt/vol) NaCl was evaluated according to the method described by Ferrari et al. (2016). After incubation at 37°C for 48 h, a color change of the culture from purple to yellow due to acidification of the substrates was considered as positive growth.

Exopolysaccharide and Diacetyl Production. For screening of exopolysaccharide (EPS) production, strains were grown in modified MRS agar medium in which the glucose present in the original formulation was replaced by 10% sucrose (Fluka, Buchs, Switzerland). Cultures were then streaked on plates that were
incubated at 37°C. After incubation for 72 h, possible EPS production was assessed based on the presence of a mucoid or ropy colony using the loop touch test described by Fguiri et al. (2016). Diacetyl production was visually determined by distinguishing a red ring at the top of the culture tubes as described by Ribeiro et al. (2014).

**Acidification and Autolytic Activity.** The revitalized strains were subcultured in sterile reconstituted goat milk (100 g/L, Meiling, Shanxi, China) to determine the acidification activity. The pH changes ($\Delta pH$) were measured after 6 h of incubation at 30°C with a pH meter (PB-10, Sartorius, Goettingen, Germany).

Autolysis was determined on cells prepared according to the method described by Scatassa et al. (2015). The autolytic capacity of the resuspended pellets was measured after 24 h of inoculation.

**Proteolytic and Lipolytic Activities.** The proteolytic activity was determined according to the procedure described by de Almeida Júnior et al. (2015). Briefly, strains were plated on the surface of skim milk agar, prepared by supplementing the plate count agar medium with 1% (wt/vol) skim milk powder. Subsequently, the strains were incubated at 37°C for 48 h. The transparent halo-forming colonies were considered positive for proteolytic activity.

The lipolytic activity was tested by cultivating strains on MRS agar with 0.1% tributyrin at 37°C for 72 h. Lipolytic activity was detected by clear zones against a turbid background of emulsified, nonhydrolyzed lipids on the tributyrin medium.

**Aminopeptidase, Dipeptidyl Aminopeptidase, and Dipeptidase Activities.** All the chemicals used in the assays were purchased from Sigma-Aldrich (St. Louis, MO) and were of reagent or higher grade. The aminopeptidase activity of the selected strains was assayed using Lys-$\rho$-nitroanilide ($\rho$NA), Glu-$\rho$NA, and Pro-$\rho$NA as substrates, as described by González et al. (2010). One unit of aminopeptidase activity was defined as the amount of enzyme capable of producing an absorbance increase of 0.001 unit. Aminopeptidase activity was expressed as the number of activity units per milligram of protein per minute. Dipeptidyl aminopeptidase activity was determined using Gly-Pro-$\rho$NA and Arg-Pro-$\rho$NA as substrates, according to the procedure described by Jensen and Ardö (2010). The activities were expressed as nanomoles of nitroaniline released per minute and per milligram of protein.

The dipeptidase activity was tested on the substrates Leu-Leu, Gly-Glu, and Leu-Pro according to the method described by González et al. (2010). The concentrations of AA released by hydrolysis were estimated by measuring the absorbance at 507 nm. One unit of activity was defined as the amount of enzyme that produced an increase in the absorbance signal at 507 nm of 0.1 unit in 1 min.

**Statistical Analysis**

Each strain was tested for growth in the presence of different NaCl concentrations in duplicate and in triplicate for the other activity tests. A one-way ANOVA analysis was applied to the results obtained from the activities, using the Student-Newman-Keuls test for comparison of the mean values ($P < 0.05$). The SPSS software package (version 16.0, SPSS Inc., Chicago, IL) was used for this purpose.

**RESULTS AND DISCUSSION**

**Identification of Lactobacilli**

Twenty-five isolates were obtained from 8 artisanal semi-hard goat cheeses collected from different Mediterranean regions (Table 1). These isolates were initially identified as lactobacilli based on the alignment success rate with the 16S rDNA sequence. Among them, 16 (2 from Ibore, 1 from Tenerife, 5 from Babia, 3 from Batzos, 2 from Xinotyri, 1 from Tulumn, and 2 from Darfiyeh) were identified as *Lb. paracasei* and 9 (1 from Ibore, 1 from Tenerife, 1 from Babia, 1 from Batzos, 4 from Sepet, and 1 from Tulumn) were categorized as *Lb. rhamnosus*. Strains of the *Lb. casei* group, notably either *Lb. paracasei* or *Lb. rhamnosus*, occur in cheese mainly as added adjunct cultures (Gobbetti and Minervini, 2014); these strains are also promising candidates for probiotic use. Interestingly, both species were previously isolated from raw goat milk cheeses (Sánchez et al., 2005; Martín-Platero et al., 2009). *Lactobacillus paracasei* was also isolated from goat milk of extensively small-scale dairy farms in Brazil (de Almeida Júnior et al., 2015). Moreover, *Lb. paracasei* was also isolated from cheeses Tenerife and Batzos (Hernández et al., 2015). However, *Lb. paracasei* and *Lb. rhamnosus* were not isolated from Sepet cheese in the previous study (Erçan et al., 2014), possibly because of differences in sampling season. Surprisingly, the studied cheeses showed distinctive organoleptic profiles, although the core microbiota of the NSLAB belonged to the same species, namely, *Lb. paracasei* and *Lb. rhamnosus*. This could be because the isolated strains possess specific physiological and technological characteristics that render unique taste to these traditional products, although they belong to species commonly used for the ripening process (Bonomo and Salzano, 2013). Our results are in accordance with
those reported by several previous studies, highlighting that *Lb. paracasei* and *Lb. rhamnosus* form the core microbiota of the NSLAB population (Fröhlich-Wyder et al., 2013; Gatti et al., 2014). This is probably due to their high tolerance toward the hostile conditions of the cheese environment during ripening, such as low pH (4.9–5.3), high salt content (4.0–6.0%), and the lack of fermentable carbohydrate (Gobbetti et al., 2015).

### Salt Tolerance

Salt tolerance is an important characteristic because NSLAB are exposed to high salt concentrations during cheese manufacturing, notably during the ripening phase (Terzic-Vidojevic et al., 2014; Carafa et al., 2015). Sodium chloride tolerance tests revealed that all strains were able to grow in the presence of 2% (wt/vol) salt (Table 1). Moreover, the results indicated that 20 strains (13 *Lb. paracasei* and 7 *Lb. rhamnosus*) could grow in the presence of 6% (wt/vol) salt. Interestingly, 10 isolates (6 *Lb. paracasei* and 4 *Lb. rhamnosus*) were able to grow in the presence of 10% (wt/vol) salt. All the 4 isolates of Sepet cheese (F-3, F-22, F-23, and F-25) were able to grow in a buffer containing 10% (wt/vol) salt, which may be related to the high salt content (14% NaCl) of the Sepet cheese. Salt tolerance (8% wt/vol salt) of *Lb. paracasei* and *Lb. rhamnosus* isolated from spontaneously fermented mountain cheese were previously reported by Carafa et al. (2015). Lactic acid bacteria uses various mechanisms for salt tolerance, such as the uptake or synthesis of a limited number of solutes (de Almeida Júnior et al., 2015). Sodium chloride is an essential ingredient used in the food industry to boost the sensory characteristics of products and to satisfy the recommended human daily intake of NaCl. Additionally, NaCl is widely used as a preservative for long storage cheeses and is important for controlling cheese ripening (Georgieva et al., 2009).

### EPS and Diacetyl Production

Lactic acid bacteria produce extracellular sugar polymers called EPS during bacterial growth, which can improve the texture and viscosity of the final product (Fguiri et al., 2016). Colonies exhibiting a slimy appearance were considered positive of EPS production. Among the isolated strains from the collected goat cheese samples, 11 *Lb. paracasei* and 6 *Lb. rhamnosus* strains were observed to produce EPS (Table 1). Corroborating our results, Ferrari et al. (2016) and Ayad et al. (2004) reported that *Lb. paracasei* and *Lb. rhamnosus* isolated from goat dairies and dairy products also produced EPS.

The ability to generate EPS is considered as an important feature for LAB used in dairy products, as smooth and creamy products are more appealing to consumers; thus, EPS production is a key feature to be considered for selecting NSLAB (Franciosi et al., 2009). In addition, EPS contributes to the water retention capacity that reduces the calorific content of the end product (Ferrari et al., 2016). From a health standpoint, EPS production by LAB received increased attention due to its immunogenic properties (Domingos-Lopes et al., 2017). Indeed, adhesion to human intestinal mucus and LAB biofilm formation are also mediated by EPS and are related to cholesterol lowering, immunomodulation, and antitumorogenic and prebiotic effects (Guidone et al., 2014). For higher production of EPS, the medium must be supplemented with considerable amounts of a carbon source; additionally, temperature and pH can affect EPS production (Ferrari et al., 2016). However, the use of EPS in the dairy industry is limited by the low yield of the product, an issue that currently remains unresolved (Ferrari et al., 2016).

In fermented food products, such as cheese, distinct flavors are generated from the microbial production of aromatic compounds. For instance, diacetyl is an essential component of many dairy products, and even at low concentrations it provides a typical flavor and a buttery aroma of cheese (Ferrari et al., 2016). Diacetyl, derived from citrate metabolism, possesses inhibitory activity against food-borne pathogens and is not present in all types of LAB (Thierry et al., 2015). In our study, more than half of the total isolates (56%) produced diacetyl. The results indicated that 53% of the *Lb. paracasei* and 67% of *Lb. rhamnosus* could produce diacetyl (Table 1). Similar results were reported for lactobacilli from Grana cheese (Monfredini et al., 2012). In agreement with our results, Nikolic et al. (2008) also observed that a high proportion of *Lb. paracasei* isolated from goat cheeses have the ability to produce diacetyl. Pérez et al. (2003) observed that 95.2% (20/21) of *Lb. paracasei* from Tenerife cheese were able to produce diacetyl, whereas 100% (2/2) of *Lb. paracasei* from Tenerife cheese in our study were able to produce diacetyl. de Almeida Júnior et al. (2015) observed that all LAB from raw goat milk samples were weak diacetyl producers.

### Acidification and Autolytic Activity

The results of the acidification activity recorded after 6 h of bacterial growth in skim milk are shown in Figure 1a. After 6 h, the isolates presented values of ΔpH ranging from 0.15 to 0.63 pH units. The results supported the values recorded for lactobacilli isolated from Armada goat cheese by Herreros et al. (2003).

\(^1+ = \text{positive reaction; – = negative reaction.}\)
In our study, 16 strains presented a slow acidification activity, with ΔpH ≤ 0.4 U after 6 h according to the classification suggested by Ayad et al. (2004). Both Lb. paracasei and Lb. rhamnosus strains exhibited slow acidification activities. A previous study showed that Lb. paracasei isolated from Tenerife cheese possessed low acidification activity (Pérez et al., 2003). Similar results were expected because lactobacilli are known to slowly metabolize lactose (Carafa et al., 2015). In general, optimal NSLAB are characterized by slow to
moderate acidification activity (Scatassa et al., 2015); high acidification activity is not favorable for NSLAB, as it would generate sensory defects in cheese.

Autolysis with the subsequent release of intracellular enzymes is a desirable trait during cheese ripening because it enhances sensory and textural properties. On the basis of the classification reported by Ayad et al. (2004), 56% strains isolated from our cheese samples were rated good (autolysis values ranging between 25 and 65%), 32% were rated fair (autolysis values ranging between 15 and 24%), and the remainder (below 14%) were rated poor (Figure 1b). The levels of autolysis for Lb. paracasei isolates ranged from 10.05 to 39.33%, with the strain G-10 showing the highest (P < 0.05) value, whereas those of Lb. rhamnosus isolates ranged between 7.2 and 44.28%, with F-3 showing the highest value. No substantial differences were observed between the 2 species. High autolytic activities, which may accelerate cheese flavor development, affect the proteolysis rate and may reduce the bitterness of cheese by hydrolyzing large hydrophobic peptides (Nieto-Arribas et al., 2010). In this respect, our isolates could be considered as interesting NSLAB candidates for cheese manufacture.

**Proteolytic and Lipolytic Activities**

Cheese quality is closely related to the proteolytic activity of the bacteria present in cheese. During milk fermentation, proteolytic enzymes produced by various LAB generate biologically active peptides and AA, which contribute to the development of the flavor and texture of the dairy product. The proteases from both Lb. paracasei and Lb. rhamnosus are less inhibited by cheese conditions, such as the presence of salt and moderately low pH, than proteinases of Lactococcus lactis (Gobbetti and Minervini, 2014). The results shown in Table 1 indicate that 9 Lb. paracasei and 6 Lb. rhamnosus strains possessed proteolytic activity. Genome analysis also showed that NSLAB encode a relatively high number of proteolytic system components, such as proteases, peptide transporters, and peptidases. In addition, Pérez et al. (2003) observed that 85.7% (18/21) Lb. paracasei from Tenerife cheese possessed proteolytic ability, whereas we observed a ratio of 100% (1/1) in our study. The isolate E-11 that presented the highest acidification activity did not present an obvious proteolytic activity; this result was also reported by other studies (Nieto-Arribas et al., 2009; Fguiri et al., 2016). Proteolysis could also contribute to the prevention of allergies observed in children under 3 yr of age due to the poor digestibility of milk proteins. However, it is noteworthy that high proteolytic activity is not always the most desired characteristic for a strain to be used in a nonstarter culture. As a matter of fact, excessive proteolysis can cause uncontrolled production of bitter peptides and other undesirable compounds, or even excessive casein hydrolysis, which would result in an excessively soft final product (Bonomo and Salzano, 2013).

None of the isolates showed lipolytic activity when assayed on tributyrin agar (Table 1). Our results corroborate those obtained by Nieto-Arribas et al. (2009), who used cream fat agar for the assay; Monfredini et al. (2012), who assayed on tributyrin agar; and Carafa et al. (2015), who used plate count agar plus milk cream for the assay. Similar results were also observed for Lb. rhamnosus from Tenerife cheese (Pérez et al., 2003). Although LAB generally possesses weak lipolytic activity, the high concentration of LAB over an extended ripening period resulted in the generation of significant levels of free fatty acids, which are precursors of volatile aroma compounds; therefore, low lipolytic activity is considered to be an important advantageous trait for cheese production (Nieto-Arribas et al., 2010). Excessive lipolysis may generate a bitter and rancid taste in cheese (Monfredini et al., 2012). Gobbetti et al. (2015) stated that, compared with primary starters, the genomes of NSLAB possess higher number of genes related to free fatty acid catabolism. This characteristic is highly desired for a performant NSLAB in cheese ripening.

For selecting the most promising NSLAB candidates, the results of the different tests performed have to be considered. A nonstarter culture should combine slow acidification activity with a high autolytic capacity. In our study, only 10 strains with low acidification activity and acceptable autolysis values were identified. Upon considering other test results, 8 strains (A-3, B-4, D-3, E-8, G-10, B-25, D-8, and F-23) presented strong NaCl tolerance, along with adequate proteolytic ability and EPS- and diacetyl-producing capabilities. Overall, these strains are promising NSLAB candidates for cheese manufacture and were thus selected for subsequent examination.

**Aminopeptidase, Dipeptidyl Aminopeptidase, and Dipeptidase Activities**

The peptidase activity of the selected LAB strains was determined to further evaluate their potential for use as NSLAB. During secondary proteolysis, the peptidolytic potential increases the amount of small peptides and free AA, the major precursors of specific flavor compounds. Aminopeptidases play an important role in the hydrolysis of bitter peptides and in AA liberation. Our results indicated that all strains showed an aminopeptidase activity toward the substrates Lys-pNA, Leu-pNA, and Pro-pNA (Figure 2a). Similarly, these
activities were also observed by Morea et al. (2007) in some strains of *Lb. paracasei*. In addition, our results were in agreement with those of Carafa et al. (2015), who indicated that *Lb. paracasei* and *Lb. rhamnosus* from the traditional mountain cheese Malga also exhibited activities toward Lys-ρNA and Leu-ρNA. However, Pérez et al. (2003), who studied the aminopeptidase activity of isolates from Tenerife cheese, observed that *Lb. paracasei* did not hydrolyze Pro-ρNA; this may be because the activity was strain-dependent. In addition, previous studies showed that *Lb. paracasei* possessed the highest aminopeptidase activities compared with leuconostoc, lactococcal, or enterococcal strains commonly isolated from cheese (Ayad et al., 2004; González et al., 2010). In our study, D-3 (*Lb. paracasei*) showed the highest activity toward Leu-ρNA, and D-8 (*Lb. rhamnosus*) exhibited the highest activity toward Lys-ρNA and Pro-ρNA. We observed that 3 *Lb. paracasei* strains (B-4, D-3, and E-8) presented higher Leu-ρNA activity than Lys-ρNA activity, whereas others had higher Lys-ρNA values than those of Leu-ρNA. It is noteworthy that these situations have been previously reported (Macedo et al., 2000; Bonomo and Salzano, 2013). The strong Pro-ρNA activities of our isolated LAB supported the hypothesis that the selected strains are of potential interest for use as NSLAB because they would release large amounts of proline from caseins during cheese ripening (Tsafarakidou et al., 2016). In contrast, the isolated strains E-8, B-25, and F-23 showed the lowest Lys-ρNA, Leu-ρNA, and Pro-ρNA activities, respectively. Converging with our results, Nieto-Arribas et al. (2009) reported that 29 of 30 strains exhibited higher activity toward Leu-ρNA than toward Lys-ρNA, whereas Macedo et al. (2000) reported higher activity toward Lys-ρNA than Leu-ρNA for the ESB230, ESB136, and ESB117 strains.

In addition to aminopeptidase, dipeptidyl aminopeptidase specifically removes proline residues from proteins (Stefanovic et al., 2017). All of the selected strains showed dipeptidyl aminopeptidase activity toward Gly-Pro-ρNA and Arg-Pro-ρNA (Figure 2b). Macedo et al. (2000) obtained the same result, indicating that *Lb. paracasei* hydrolyzes Gly-Pro-ρNA and Arg-Pro-ρNA. Reports show that *Lb. paracasei* isolated from Tenerife cheese was able to hydrolyze Arg-Pro-ρNA (Pérez et al., 2003). Moreover, *Lb. rhamnosus* also possesses a proteolytic system including the X-prolyl-dipeptidyl aminopeptidase (Moslehishad et al., 2013). The strain D-8 (*Lb. rhamnosus*) exhibited the highest activity toward both Gly-Pro-ρNA and Arg-Pro-ρNA.

Our results show that each strain of the selected LAB exhibited a different dipeptidase activity (Figure 2C). Notably, the Leu-Leu peptidase activity of all strains was higher compared with those observed with other

[Figure 2](#) Peptidase activity of the selected lactic acid bacteria isolates from semihard goat cheese samples (as identified in Table 1). (a) Aminopeptidase activity is expressed as AP units, which correspond to an increase of 0.001 unit of the absorbance signal in 1 min for each milligram of protein. (b) Dipeptidyl aminopeptidase activity is expressed in nanomoles of nitroaniline released per milligram of protein per minute. (c) Dipeptidase activity was expressed as DP units, which correspond to an increase of 0.1 unit of the absorbance signal per minute per milligram of protein. ρNA = ρ-nitroanilide.
substrates. Our results are in accordance with that reported by González et al. (2010). Highest dipeptidase activity was observed for the isolate D-8 (Lb. rhamnosus). In view of the peptidase activity of these selected strains, A-3, A-4, D-3, and D-8 may be of interest, owing to their strong action.

The substrate specificity and extent of the peptidase activities are strain-dependent. Jensen and Ardö (2010) demonstrated that the growth medium may play a significant role in the peptidase activities of lactobacilli. The combination of proteases and peptidases permits the release of free AA, and the protease activity is generally weaker than the peptidase activity (Gobbetti and Minervini, 2014). During long ripening times of cheeses, free AA are catabolized into chemical compounds (e.g., aldehydes, ketones, alcohols, low-molecular weight sulfur compounds), which, in turn, markedly affect the sensory properties of cheese (Gobbetti and Minervini, 2014). The joint activity of peptidases and proteases is critical to achieve the desired level of proteolysis in cheeses.

**CONCLUSIONS**

Artisanal goat cheeses harbor diverse LAB with different properties. Our study successfully isolated, identified, and characterized the LAB from different raw goat milk cheeses for selecting potential nonstarter LAB strains. The results indicated that LAB belonging to either Lb. paracasei or Lb. rhamnosus showed maximum promise for manufacturing goat cheese. On the basis of the characterization of the isolated strains, 8 strains presented an acceptable resistance to high salt concentration, EPS and diacetyl production capacities, high acidification activity and autoysis, proteolytic ability, and nonlipolytic activity, and were therefore selected for further peptidase activity assay. The selected strains showed aminopeptidase, dipeptidyl aminopeptidase, and dipeptidase activities, although their hydrolysis capacities varied. Finally, 4 strains (A-3, B-4, D-3, and D-8) showing the best characteristics could be considered as NSLAB for industrial manufacturing of goat cheese.
