**ABSTRACT**

Low total blood calcium concentration after calving has been demonstrated to be a risk factor for reduced neutrophil function. The objective of this study was to evaluate whether administration of an injectable calcium supplement product soon after calving increased neutrophil oxidative burst or phagocytosis capacity. Cows (n = 27) from 4 farms were blocked by parity and randomly assigned to receive either calcium gluconate (35% wt/vol) in combination with calcium glucoheptonate (10% wt/vol; Theracalcium, Vétoquinol Canada Inc., Lavaltrie, Quebec, Canada) or a placebo within 12 h after calving and again 24 h later. Each dose of 120 mL was injected subcutaneously over 2 sites. Total serum calcium concentration, neutrophil oxidative burst, and neutrophil phagocytosis capacity were measured from coccygeal blood samples before (time 0) and 72 h after first treatment. There was no difference between treatment groups in lactation number, total calcium concentration, oxidative burst, or phagocytosis at time of enrollment. There was no effect of treatment on oxidative burst or phagocytosis by neutrophils. This preliminary study does not support an effect of supplemental calcium to improve neutrophil oxidative burst or phagocytosis capacity of low-parity parturient cows.

**Key words:** calcium supplementation, immune function, transition cow

**Short Communication**

In the 72 h after calving, most dairy cows have reduced blood calcium concentrations. This transitory reduction is a result of a sudden substantial demand for calcium from the plasma pool at the onset of colostrum and milk production. Initiation of homeostatic mechanisms to restore circulating blood calcium to normal levels take several days, with the nadir of blood calcium concentrations occurring 12 to 24 h following parturition (Goff, 2008). Ionized calcium is important for messaging in cell metabolism and proliferation through changes in cytosolic ionized calcium concentrations. Intracellular calcium signaling is a key element in immune cell activation through influx of calcium from the extracellular space when antigen receptors are triggered (Vig and Kinet, 2009). In vitro, low extracellular ionized calcium was associated with decreased phagocytosis in bovine neutrophils (Ducusin et al., 2003). Kimura et al. (2006) demonstrated that mononuclear cells of periparturient cows have lower intracellular calcium stores, resulting in blunted calcium release in response to immune cell activation signals. Reduced calcium release in response to an immune cell activation signal likely contributes to periparturient immune suppression, but the reduced immune function that is experienced by almost all transition dairy cows with varying severity (Kehrli et al., 1989) is multifactorial and not well understood.

A decrease in circulating neutrophil oxidative burst activity postpartum has been found in cows that develop metritis (Hammon et al., 2006) and endometritis (Mateus et al., 2002; Hammon et al., 2006). Similar to other immune cells, an increase in intracellular calcium concentration is an early event in neutrophil activation (Burgos et al., 2011). Martinez et al. (2012) found neutrophil number, oxidative burst, and phagocytosis capacity to be reduced among cows with a blood calcium <2.15 mmol/L between 1 and 3 DIM. These cows were also at greater risk of metritis. Supporting neutrophil function to reduce postpartum metabolic and reproductive disease is desirable, but it is unclear to what extent prevention or treatment of hypocalcemia may contribute. Prophylactic calcium supplementation, which is commonly administered to parturient dairy cows to reduce the incidence of clinical hypocalcemia, may be one way to achieve this. The objective of this study was to evaluate whether administration of an injectable calcium supplement product soon after calving increased neutrophil oxidative burst or phagocytosis capacity.
A randomized controlled trial was conducted using parturient cows from 4 commercial dairy farms in Ontario, Canada, in June 2014. Herds were purposively selected based on proximity to the University of Guelph, willingness to comply with the calcium supplementation protocols, and herd size such that there would be cows available to enroll that had calved within the 12 h before the technician’s visit. Producers agreed to refrain from using other forms of prophylactic calcium supplementation in enrolled cows and consented to a study protocol that had been reviewed and approved by the University of Guelph Animal Care Committee. All herds fed a TMR and prepartum cows did not receive anionic dietary supplements. The sample size for this proof-of-concept study was 13 cows per treatment based on detecting a 10% point difference (SD = 9) in mean proportion of neutrophils performing oxidative burst.

Cows including first-parity animals that had calved in the previous 12 h were enrolled on the first day of the week for 3 consecutive weeks. Cows that showed signs of milk fever or injury related to calving or had already received a calcium supplementation product were excluded. Cows were randomly assigned to receive the calcium supplementation product or a placebo. Cows were the difference between the samples and negative control. A gate was placed around ≥97% of neutrophils in the negative control of neutrophils incubated without fluorescent beads.

Cows in the treated group received calcium gluconate (35% wt/vol) in combination with calcium glucoheptonate (10% wt/vol) for a total of 9.46 g of calcium (Theracalcium, Vétoquinol Canada Inc., Lavaltrie, Quebec, Canada) given in 2 doses (within 12 h after calving at enrollment and again 24 h later). Each dose was 120 mL injected over 2 sites (60 mL per site) subcutaneously. Cows in the control group received a similar volume of placebo (medication vehicle solution with no active ingredient) at time of enrollment as a continuous variable and a di-
Short Communication: Effect of Calcium Supplementation at Calving

A dichotomous variable above and below the cut points of 2.0 and 2.15 mmol/L were offered as covariates to each model, and pretreatment oxidative burst or phagocytosis value at time 0 was controlled for as a covariate in each model. Variables remained in the final model if the \( P \)-value was \( \leq 0.1 \). Interactions of these covariates with treatment were tested and retained if significant \( (P \leq 0.05) \).

A total of 29 animals were enrolled in the experiment. Two animals were unavailable for follow-up samples at 3 DIM due to death \( (n = 1) \) and culling \( (n = 1) \). There was no difference in lactation number, total calcium concentration, oxidative burst, or phagocytosis at the time of enrollment between treatment groups \((P > 0.2; \text{Table 1})\). Of the 29 animals enrolled, 23 were first parity, 5 were second parity, and 1 was third parity. Enrollment from the 4 farms resulted in 11, 1, 3, and 14 cows from farms 1, 2, 3, and 4, respectively. The time between calving and first treatment as well as the interval between injections of the 2 doses of calcium did not differ between treatment groups \((P > 0.65)\).

The prevalence of subclinical hypocalcemia at enrollment was 38\% using a cut point of 2.15 mmol/L \((n = 11; 6/23\) primiparous and 5/6 multiparous). A cut point of 2.0 mmol/L characterized 24\% of cows as subclinically hypocalcemic \((n = 7; 3/23\) primiparous and 4/6 multiparous). At 3 DIM there was no difference in mean calcium concentration between groups \((P = 0.62)\). The mean in vitro oxidative burst and phagocytosis \((\% \text{ of neutrophils}) \pm \text{ standard error}\) are displayed in Figure 1. There was no effect of treatment on oxidative burst \((P = 0.64)\) accounting for oxidative burst at time 0, and there was no effect of treatment on phagocytosis \((P = 0.19)\) accounting for phagocytosis at time 0. There was no interaction \((P > 0.30)\) of treatment with pretreatment blood calcium concentration (as a continuous variable or classified as <2.0 or 2.15 mmol/L).

We hypothesized that treating cows with supplemental calcium would mitigate some of the expected reduction in neutrophil function. The results suggest that supplementation of parturient cows with subcutaneous calcium would mitigate some of the expected reduction in neutrophil function.

### Table 1. Blood calcium concentrations and measures of neutrophil function on d 0 and 3 relative to calving in 27 dairy cows that received calcium supplementation or a placebo within 12 h of calving and 24 h later

\(^1\)Oxidative burst was measured as the percentage of cells activated by phorbol myristate acetate, evaluated using flow cytometry.

\(^2\)Phagocytosis was measured as the percentage of neutrophils that phagocytosed \( \geq 1 \) fluorescent bead, evaluated using flow cytometry.
calcium as given here does not improve oxidative burst capacity or phagocytosis of the neutrophils.

The degree of hypocalceemia among the study sample was moderate, with 38% of animals having tCa <2.15 mmol/L and 24% having tCa <2.0 mmol/L immediately before treatment. In 657 cows from 7 herds sampled at a similar time in the same region, we found 59% of cows with tCa <2.15 mmol/L (Miltenburg et al., 2016). Martinez et al. (2012) found that tCa <2.15 mmol/L was associated with poorer neutrophil oxidative burst and phagocytosis capacity. Therefore, cows in our sample were at risk for improvement in neutrophil function if the calcium supplement was able to affect this. Although tCa was not characterized in the 12 to 24 h after treatment, a previous study demonstrated that the calcium supplement used in the current study significantly increased tCa in treated cows compared with a control group at 24 h after enrollment, and cows in the treatment group with a lower tCa at enrollment had a greater increase in tCa at 24 h (Miltenburg et al., 2016).

In the present study, overall oxidative burst capacity did not differ with treatment or between the 2 time points measured, but it varied widely among individual cows. The mean proportion of neutrophils showing oxidative burst was low on the day of calving (13%); however, more than half the cows had lower oxidative burst at 3 DIM than at calving, consistent with the nadir of function occurring after calving. Mean phagocytosis capacity increased between the 2 time points measured, but two-thirds of the cows had declining phagocytosis capacity between the 2 time points. This is consistent with a decline in phagocytosis around 1 wk postpartum (Kehrli et al., 1989; Kim et al., 2005; Sander et al., 2011).

Neutrophil life span is short, with cells lasting no more than a few days before being replaced (Kolaczkowska and Kubes, 2013). After production and differentiation in the bone marrow, it is unclear whether calcium concentrations can be altered in circulating neutrophils. When neutrophils were treated with the anticoagulant EDTA, an extracellular calcium ion chelator, neutrophil phagocytosis capacity was severely reduced (Ducusin et al., 2001). Previous work has suggested that cows with reduced calcium concentrations in blood are unable to replenish intracellular calcium and have less calcium in the endoplasmic reticulum available to affect cytosolic concentrations, thereby compromising neutrophil activation and the generation of reactive oxygen species (Ducusin et al., 2003; Martinez et al., 2012). These studies lead to the hypothesis that raising the total blood calcium concentration would alter this pathway. A greater understanding of the mechanisms by which neutrophils take up calcium in bone marrow or in circulation is needed to understand the potential to effect improvements in intracellular calcium and in neutrophil function. It is possible that the supplementation did not increase total blood calcium enough to effect change in intracellular calcium concentrations. It would be beneficial to measure the intracellular calcium concentration of neutrophils from supplemented cows versus controls to establish whether higher intracellular calcium was achieved.

A flux of intracellular calcium from the extracellular space to intracellular space is part of neutrophil activation; however, calcium-independent signaling pathways by means of protein kinases are also present (Sayeed, 2000). Cytosolic calcium is required to initiate phagocytosis (Sayeed, 2000) as well as the fusion of secondary granules with the phagosomal membrane (Jaconi et al., 1990). Furthermore, cytosolic calcium is required in the production of reactive oxygen species through activation of NADPH oxidation (Bréchard and Tschirhart, 2008). However, because neutrophil activation is not solely calcium dependent, a calcium supplement intervention might not be sufficient to affect neutrophil function when compromised peripartum immunity is multifactorial. Furthermore, if neutrophil oxidative burst function begins declining 2 to 3 wk before calving, an intervention on the day of calving may be too late to effect change in neutrophil function. As the neutrophil life span is short and neutrophils circulating during this time are of lower oxidative burst capacity, increasing blood calcium concentration for 6 to 12 h through supplementation, even if this increases neutrophil intracellular calcium, might not be enough to effect meaningful improvement in immune defense and the overall health of the cow.

It is not clear whether different results would be achieved using a population of cows at greater risk of hypocalceemia, such as cows of greater parity. As risk of hypocalceemia increases with age or parity, an improvement in immune defense from calcium supplementation might be evident in older cows compared with the current sample, which by chance was skewed toward younger cows. Additionally, a larger sample that includes a greater number of cows at risk of reduced immune function, such as higher-producing cows and those at high risk of postpartum uterine disease, might yield different results. The main effect of calcium status at the time of enrollment and its interaction with treatment did not remain in the oxidative burst or phagocytosis models as an explanatory variable, suggesting that the effect of treatment was not different between subclinical and normocalcemic cows. Calcium status was explored using both the cut point of 2.0 and 2.15 mmol/L but without finding an effect. However, this should be explored more fully, potentially by
enrolling and blocking cows by initial calcium status. The current research design did not allow characterization of the duration of hypocalcemia. It is possible that cows that were normocalcemic at enrollment became hypocalcemic at some later point. This information is relevant to understand the true incidence of subclinical hypocalcemia and the effect of calcium supplementation in normocalcemic versus hypocalcemic cows. Finally, interventions that produce a more sustained and earlier increase in blood calcium, such as feeding a prepartum diet with anionic salts to achieve a negative DCAD, would be worth investigation. A recent study found some benefits for neutrophil function (Martinez et al., 2018). This preliminary study does not support an effect of supplemental calcium, as given to low-parity parturient cows, to improve oxidative burst or phagocytosis capacity of neutrophils.

ACKNOWLEDGMENTS

This study was funded by Vétoquinol Canada (Lavaltrie, Quebec, Canada) with student stipend support from the Ontario Ministry of Agriculture, Food and Rural Affairs (Guelph, Ontario, Canada). The authors thank the participating farms, technicians, and students.
